WHY SYPHILIS IS NOT ABORTED BY THE EARLY DESTRUCTION OR EXCISION OF ITS INITIAL LESION.[1]

BY R. W. TAYLOR, M.D.,

CLINICAL PROFESSOR OF VENEREAL DISEASES AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

I KNOW of no better text as a prelude to this essay than the following statement recently made by that learned syphilographer of Paris, Dr. L. Jullien. He says:[2] "I believe in the possibility of interrupting or attenuating the course of syphilis at the time of its initial sclerosis, that we should not fold our arms during the period in which a patient's existence is to be decided, or to think that all is lost before anything has been commenced. This is the principle to which reasoning and experience have conducted me." From a very early date the idea of aborting syphilis by various means was entertained by surgeons, and this idea has prevailed until the present day. Ten or twelve years ago excision of chancre as a prophylactic measure was largely practised and the communications are very numerous bearing upon the subject. The consensus of opinion among advanced syphilographers of to day is that the operation is utterly futile, and only a small number, and among them M. Jullien, still cling to the opinion that syphilis may thus be suppressed. In round numbers, in medical literature, about four hundred and sixty odd cases of excision of syphilitic chancres have been reported, and of these one hundred and six have been claimed as being successful. I have held for many years that the operation (useful in some cases as a therapeutic procedure) is utterly valueless as a means of destroying syphilis, and I have been searching for a long time the reason why. It appears to me that I have now learned the reason why thoroughly applied caustic and thermal destruction and generous excision have failed to limit syphilis to its early stage, and I shall here present the evidences of my belief. In order to make the subject clear to those not familiar with the literature of excision of chancre I shall here interpolate four cases, two personal and two reported by other observers, in which, seemingly, under the most favorable circumstances, destruction and excision was performed without in any manner staying the course of the disease. I will first quote two of my own quite numerous cases: A patient came to me with a minute, slightly elevated, excoriated papule, not larger than the heads of four pins. The patient, a young man, was of a very nervous temperament, and very anxious about his sore, which he had seen for the first time that day. Twenty days before he had had connection with a woman whom I examined, and found a disappearing chancre on the right labium minoris, just above the fourchette, and a roseolous syphilide, typical in all particulars, on the body. I informed the gentleman that his sore was in all probability syphilitic in nature. At his request I excised it, taking the following stringent precautions to do the operation thoroughly: Previous to cutting the penis was washed with soap and water and then with carbolic acid water (five per cent.). The sore was touched with pure nitric acid in order to destroy its virus and to prevent its exudation into the adjacent healthy tissues. It was then dusted with calomel, its base transfixed and cut away together with a liberal margin of healthy tissue. The wound, carefully kept from contamination of any kind, healed by granulation in about ten days. In spite of this, induration of the inguinal ganglia commeneed and was typical in extent and hardness thirty days after the operation. Forty-two days after the date of the discovery of the chancre the patient presented general syphilitic manifestations. This case is given in my treatise on venereal diseases.[1]

Another case, and a more recent one, is equally striking in all its features. A gentleman, aged thirty, came to me early in 1889 in great distress of mind concerning a lesion on his penis which he had noticed for the first time the night before while taking a hot bath. The reason of his fear and worry was that a friend had a few days before informed him that he had contracted a hard chancre from a woman with whom he had learned he (my patient) had had intercourse. Upon examination I found on the dorsum of the penis a very minute (one-tenth inch long) fissure of a dull violaceous color. I could discover no change in the inguinal ganglia. At his urgent request I examined the woman and found just within the vagina, in the sulcus to the right of the urethra, a red and inflamed patch, the seat of considerable thickening. In the light of what I found besides, I diagnosticated it as a declining hard chancre, of which I had seen many similar before. There was marked inguinal adenitis and a very faint disappearing roseola, a mucous patch on the right pillar of the fauces, and a slight falling out of the hair. The certainty of the syphilitic nature of the sore on the patient's penis, which appeared seventeen days after coitus, being so convincing, its probable character was announced to him. The condition of the skin of the penis was such that the little fissure could be cut away by means of a very liberal elliptical incision, and no harm would be done to the integrity of the organ. Under the most careful technique, with thorough antisepsis, I excised a piece of skin half an inch wide and three-quarters of an inch long on the evening of the day upon which the fissure was first noticed, and seventeen days after the infecting coitus. Examination of the patient was made almost daily. The wound healed kindly under iodoform and gauze, and was not followed by any induration in the minute scar which was formed. It was fully twenty days after the operation that well-marked inguinal adenopathy could be made out. In fifty-two days after the first appearance of the chancre well-marked secondary manifestations were observed.

These cases, and many others which I have thus treated over a period of many years, with a like result, convinced me that even with the most painstaking, early, and generous excision, syphilis could not be suppressed or aborted.

In this connection, to lay emphasis to my remarks, I will quote the old-time case of Berkeley Hill, and the more recent one of Rasori, as they will serve the purpose of cumulative evidence, if such is needed. Berkeley Hill says:[2] "In July, 1858, a gentleman came to me with the following story: That morning, about four o'clock,

[1] Read before the New York Academy of Medicine, May 21, 1891.
[2] De la possibilité d'enrayer la syphilis après l'apparition du chancre induré, Bulletin Médical, 1891, No. 5, p. 35.

[1] Bumstead and Taylor, p. 510. Philadelphia, 1883.
[2] Syphilis and Local Contagious Disorders, pp. 76, 77. London, 1881.

during violent intercourse, he had felt a sudden snap. On awakening a few hours later he found that the frænum had been torn across, and that he had bled freely. This made him anxious to know if there were any means to insure him against syphilis. At 3.30 P.M. of the same day I examined the part and found the frænum torn and the wound slightly swollen, but otherwise quiet enough. Ricord's views were then in vogue—that destruction of the sore within five days of its existence would prevent syphilis, and I assured him that cauterization would remove all danger of the disease. To make sure, I destroyed a considerable layer of tissue with fuming nitric acid. In due time the eschar separated. The surface healed very quickly, and my patient's satisfaction was extreme. This was at the end of July. In the latter part of August he called again and showed me the cicatrix, which he said he had noticed that morning to have altered. It was clearly indurated. Presently the glands in the groin enlarged, general syphilis followed, and lasted a couple of years."

It certainly must be confessed that all the circumstances in this case were very favorable to the annihilation of the syphilitic virus in that torn surface, and that all that energetic cauterization could do had been done without avail. This case stands as a classic, pointing out the futility of very early and active cauterization in preventing syphilis. It must be said, however, that this man tore the most vulnerable part of the penis, where the vessels are very numerous and the lymphatics very extensive and superficially situated. It proves very conclusively that under such conditions syphilis loses no time in gaining a foothold in the system.

Let us us now quote the case of Rasori, which has had much weight in establishing the fact of the inutility of excision as a means of suppressing syphilis. Rasori[1] says: "A lawyer, aged twenty-eight, of robust constitution, came to him in February, 1881, and desired him to examine a woman with whom he had cohabited two hours before and whom he suspected to be syphilitic. Examination showed that she had extensive condylomata lata and a generalized roseola. Twenty-eight days elapsed, during which the anxious man examined himself minutely and bathed his penis so vigorously with antiseptic lotions and nitrate of silver solutions that he almost produced a severe balanoposthitis. On the evening of the twenty-seventh day the mucous membrane seemed normal, but the following morning he presented a little red lenticular papule the size of a hemp-seed on the internal layer of the prepuce toward the right. At the request of the patient Rasori immediately excised the lesion, together with a liberal amount of the surrounding tissues. The wound was irritated by the foolish exploratory manipulations of the patient and did not heal until the twenty-fifth day after the operation. Before this, however, the ganglia had become perceptibly swollen. Forty-eight days after the operation unmistakable generalized manifestations of syphilis appeared."

Gibier and Mauriac also excised chancres forty-eight hours after their appearance, yet syphilis followed in each case. Several other similar cases have been reported in the rich literature of the subject.

In spite of these seemingly convincing results some observers still regarded the chancre as a local lesion and favored an abortive treatment.

Let us now consider my further experience.

The following personal case I will give with considerable detail, for upon it largely hangs the conclusions reached in this essay. On January 3, 1890, a gentleman came to me wishing to make an appointment for a date upon which I could circumcise him. At that time I made a preliminary examination of his penis and on the free border of the prepuce I found a small, brownish-red, not excoriated papule, no larger than the head of a small tack. It struck me instantly that he had a hard chancre, for I had many times seen almost precisely such an insignificant lesion develop into a true syphilitic sclerosis. The patient was positive that when he took his bath on the previous morning there was no spot on his penis and he thought there had been none in the evening. So circumstances seemed to warrant the view that it began in the night.

Upon questioning the gentleman I obtained the following facts: He lived in the suburbs of a large Southern city, and, as a rule, when he went to town he cohabited with a woman in some first-class house. He had been at his home, and had for a period of three months prior to December 20, 1889, been perfectly continent. On that date he went to the city, transacted business during the day, and passed the night in the embraces of a lady of the town, whom he had been assured was perfectly clean and healthy. He had no further sexual intercourse until the time of his first visit to me, just fourteen days after this last coitus. At the consultation I explained my suspicions, thus fortified by a very clear and conclusive history, and urged the operation, thinking in my own mind that if ever there was a favorable opportunity for testing the value of excision of chancre as a prophylactic for syphilis this was the case. It so happened that business of importance delayed the operation until January 7th, four days after the appearance of the chancre and eighteen days after the inoculation of the syphilitic infection. At this time no perceptible enlargement of the inguinal ganglia could be felt, a symptom looked for and also not found four days previously. The prepuce was removed, and owing to its marked redundancy fully one and one-half inch of tissue was ablated. Healing took place promptly in a week, and no traces of induration were to be found in the cicatrix. Plenty of tissue remained to allow of full erections. The patient was watchful of himself and constantly came for inspection. On January 17th I thought I detected slight enlargement of the inguinal ganglia; but on the twentieth of that month the adenopathy was very evident. From that date it increased until it became typical in all particulars. On February 21st a typical roseola appeared, which had been watched for daily during the preceding fortnight. At this time the ganglia in the neck and at the elbows were perceptibly enlarged and typically syphilitic. Prior to the evolution of the secondary period of syphilis I found very minute but hard cords running up the dorsum of the penis. The nature of the excised papule was therefore proved beyond doubt, and I congratulated myself that I had placed in a proper fluid for preservation and examination that redundant but precious prepuce.

I placed the morbid specimen in the hands of Dr. Van Gieson, with a view of learning all that was possible of the microscopic anatomy of the hard chancre at the earliest period of its development, and also of finding out if possible why it was that in spite of this early and thorough ablation of the prepuce upon which the chancre was seated syphilis had not been suppressed or aborted. At a later date I gave him a prepuce upon the lower part of which, near the frænum, was a typical hard chancre. In this case the incubation had been of sixteen days' duration and the chancre was ten days old when it was excised. Consequently it presented the evidence of an infection which took place twenty-six days previously. In my judgment these two specimens are ample for the purpose of studying the early successive stages of syphilitic infection. I have learned from study years ago that when fully matured the initial sclerosis does not lend itself readily to microscopic examination. The tissues become so dense and compact that a clear idea cannot very often be gained of the relation of the composing structures. The microscopical appearances of these specimens is thus given by Dr. Van Gieson:

"*Microscopical Examination.*—In the first case there is a circumscribed mass of tissue, resembling in structure ordinary granulation tissue, about one-eighth of an inch in diameter, in the upper layers of the skin. The epidermis

[1] Escissione di un ulcero duro alla 12a ora della sua apparizione, Giornale italiano delle mallattie veneree e della pelle, 1881, p. 343 et seq.

vessels, because the whole skin is more or less uniformly infiltrated with proliferating connective tissue cells, or such as the ulcer is composed of in the first and earlier case. This extensive diffuse infiltration merges in with the perivascular cell-clusters, so that their origin and distribution is less clearly marked than in the first cases.

"In the second case, however, the excised portion was even larger than in the first case, and the sleeves of cells about the blood-vessels could be traced to a greater distance from the point of infection.

"The great value of the first specimen is the very early stage of the infection, where the distribution of the tissue composing the lesion is so limited and circumscribed that the stage of development and arrangement of the perivascular cell investments can be studied clearly and fully. In chancres of later duration the diffuse infiltration of the skin is extensive and condensed, and it obscures the study of the blood-vessel changes, but even in these later chancres the blood-vessels, either at a distance from the initial lesion or around the edges of a focus of granulation tissue, show the same accumulation of cells in the perivascular spaces.

"The point deserving of attention in the first case is the extremely early and far extending involvement of the blood-vessels. Although the primary sore in this first case is but of a few days' duration and very small, and under the microscope is of such limited and circumscribed extent, the blood-vessels are very extensively surrounded by cell investments at a considerable distance from the ulcer. The microscope shows how deep rooted syphilis is at the very beginning of the sore, by having propagated itself along the perivascular lymph spaces, and how futile it is, as experience has already shown, to attempt to stay syphilis by excising the primary sore. Apparently, judging from the appearance of the vessels in this case, their involvement begins before the appearance of the sore.

"The microscopical analysis of the case also shows how it is that the infection of syphilis travels from the primary sore and infects the body. The perivascular spaces are lymph-spaces which communicate ultimately with the inguinal glands and the enlargement of these glands is undoubtedly due to the advancement of this cell proliferation along the perivascular spaces until it reaches these lymph-glands, and possibly the same process extends from the inguinal to another set of glands or lymphatics.

"Whatever the causal agent of syphilis is, it very soon reaches the perivascular spaces and travels along these spaces, or it initiates a proliferation of cells about the vessels which rapidly propagates itself along the perivascular spaces to more distant tissues."

The foregoing facts can be very clearly understood by the study of Figs. 1 and 2. In the central upper part of Fig. 1 the chancre is shown, composed of a mass of small round cells. It seems to be quite sharply marginated and on each edge to be still covered with epithelium. Well down under the chancre the small veins are seen to be involved and surrounded by their coat-sleeve like sheath of small round cells. The blood-vessels are shown in this figure as red spots, and the black dots around them correspond to the proliferated cells, which are placed in the manner already described. Then beyond the margin of the chancre we find the same condition of the vessels in skin which to the eye seemed normal. Therefore in this figure (No. 1) we see that as early as the fourth day of its appearance the chancre is well on its way to full development. But, further than this, it is apparent that the same morbid process is scattered around and beyond its margin. If the specimen had been studied alone, with a view of determining how widely and how deeply we should cut in the prophylactic excision of chancre, we might conclude that taking in considerable space beyond the chancre and deeply down to the fascia would be sufficient. But we pushed the investigation still farther, as shown in Fig. 2. This is an exact representation of sections taken from the skin of the prepuce at points remote from the chancre, a distance of nearly an inch, and which to the naked eye in life looked perfectly normal. In this figure we find the same morbid process going on. The rete is quite thickly studded with the infecting cells, and the vessels in the subcutaneous tissue are also, with one exception, involved in the same process as those near the chancre. At the bottom of the figure there are a number of these infiltrated vessels, a fact which shows how deeply the infective process had extended. There is abundant evidence from many careful observers to prove that the invasion of the syphilitic poison takes place by way of the veins chiefly, in a less degree with the arteries, and also by way of the lymph-spaces. These specimens show this very clearly.

The facts brought out in the examination of the second specimen, representing the infective process twenty-six days old, are fully confirmatory of the results found in Figs. 1 and 2. The specimens show that at a distance of fully an inch and a half from the chancre the cell-changes around the vessels are very marked and in active stage of proliferation.

These studies, therefore, go to show that in the very first days of syphilitic infection, as shown by the chancre after the first period of incubation, the poison is deeply rooted beneath the initial lesion, and that it extends far beyond it; that it is in a most active state and, running along the course of the vessels, it soon infects all the parts beyond, even to the root of the penis. These studies seem to warrant the conclusion that the virus is not localized to its point of entry and that it does not shut itself in by throwing out a dense wall of circumvallation, which later on disappears and allows of the exudation of the morbid products of the heretofore supposed closed-in morbid focus. Clinical and pathological facts go to show that the infective process occurs very rapidly. Berkeley Hill's case comes in here with significant teaching. So rapid had been the infection that very complete destruction of the torn surface only twelve hours after the infecting coitus failed to suppress or abort the disease.

The cases of Rasori and my own foregoing ones show very clearly that it is utterly futile to rely on excision as

a prophylactic measure after the chancre has appeared. The poison seems to strike at once for the smaller vessels, chiefly the veins, and to run along them with great rapidity, and with exuberant growth. Therefore, contrary to the ideas hitherto held, it is certain that in the first period of incubation the infection is going on rapidly and actively by diffusion, instead of, as we formerly supposed, smouldering in a cold and aphlegmasic manner in a sharply limited space.

To my mind, therefore, the facts presented show very clearly that the infection-process in syphilis is, from the very beginning, one of constant growth and diffusion. In support of this, I think I can with advantage present some results of the study of the so-called lymphatic cord of syphilis, which, according to the old ideas, running from the storage-battery, as we may figuratively here term the chancre, along the dorsum or sides of the penis to the groin, empties into the inguinal ganglia the infectious material gathered up by the radicles. These studies have been made by Dr. Külneff,[1] of St. Petersburg, under the auspices of Professor Tarnowsky, who has excised portions of five of these cords, taken from patients having true hard chancres about the prepuce and glans. These cords varied in size from a knitting-needle to a lead-pencil, and were situated just under the skin in the loose connective-tissue, as we usually find them. The chancres were from a fortnight to two months' duration. The morbid changes found in these excised cords are substantially the same as those shown in my figures, Nos. 1 and 2. Külneff reaches the following conclusions: 1. The cord occurring in cases of primary syphilitic sclerosis results from inflammation of the subcutaneous veins of the penis. In other words, it is a manifestation of syphilitic endo- and peri-phlebitis. 2. The morbid process commences primarily in the vein, probably in its interior, which becomes vascularized and densely infiltrated with epithelial or granulation-cells, accumulating especially on its periphery, close to the muscular coat, where they form thick layers. The endothelium undergoes hyaline degeneration and the vascular lumen is filled up with a thrombosis. Consecutively, both the media and adventitia, as well as the adjoining connective-tissue, becomes intensely infiltrated with granulation-cells, which show a distinct tendency to transformation into young connective-tissue corpuscles. The small-sized veins in the vicinity are found to be blocked up with red blood-corpuscles and surrounded with minute extravasations, while the arteries are seen to be empty or collapsed. 3. The size of the syphilitic cord in the same stage of the process is dependent upon the intensity and extent of the inflammatory process. 4. The tendency of the cell-infiltration to pass into young connective-tissue elements seems to point out that the nature of the morbid process is identical with that of the initial syphilitic sclerosis. 5. The development of the cord should be regarded as an early manifestation of vascular lesions in syphilitic patients.

The gross appearances of these cords, and their relation as to the size of the lymphatics, is well shown in Figs. 3 and 4, which are exact reproductions from Külneff's essay.

It will be seen that the results of the examinations of my cases of very early syphilitic infection dovetail completely and conclusively with those of Külneff, who studied tissues farther up the penis which were the seat of older infection. The conclusion is warranted, I think, that the changes which take place in the chancre and small radical vessels run up quite promptly to the larger efferent vessels and largely through them is the poison carried into the system.

Ricord,[2] in his later years, has said that he considered the destruction of the infecting chancre as absolutely

RIVER BATHS IN WINTER.[1]

By A. ROSE, M.D.,

NEW YORK.

In his inaugural address our President mentioned among other antiseptic remedial agencies of internal medicine that of cold baths; its importance in infectious febrile diseases, its beneficial effect upon the circulation, its power to relieve the hyperæmic brain, thereby restoring consciousness and keeping off stupor, somnolence, and coma.

In contradistinction to this I desire to relate herewith the effects of cold baths in somewhat unusual form upon the healthy individual.

Twelve years ago, or more, I began taking cold baths in the house during the winter, and noticed a greater degree of well-being the colder the water had been; the only trouble I experienced during the first winter was a rheumatoid pain in the right ankle, whenever I had bathed on a cold, rainy day. These pains, at first not severe, remained for days, and inasmuch as they seemed to recur in rainy weather I ceased bathing on such days.

During the second winter the pains became more severe after bathing on rainy days; they appeared suddenly while walking in the street, compelling me to return home with some difficulty.

The application of an ice-bag for about fifteen to thirty minutes would relieve me so that I was able to move about again without impediment. The attacks were entirely confined to the right ankle-joint.

During the third winter, and ever since, I have been entirely free from rheumatoid pain in the right ankle. Bathing in cold water, even during the coldest weather and on rainy days, could be indulged in with impunity.

Until four years ago it had not been suggested as yet — at least I was not aware of its having been stated—that diseases of frigeration and some painful affections of the

[1] Paper read before the German Medical Society of New York, April 6, 1891.

locomotory organs were to be distinguished from real rheumatism.

Aside from these pains I had quite a pleasant experience. Formerly I had frequently been a victim of severe nasal catarrh, but the cold baths had gradually relieved me from the tendency thereto.

Five years ago it so happened that I was called during the month of March to the sea-coast at Rockaway Beach. I had to remain over night, and found lodging in an old barrack in a space having a large opening toward the sea. My couch was hard, other covering than my own clothes was not at hand, and consequently "omnia mecum portans mea," I retired. The night was pretty cold. Accustomed to exposure to weather of all kinds, I was not aware of any discomfort; on the contrary, I felt very well in the fresh sea-air, in spite of the crude surroundings.

During the night I awoke and gazed upon the beautiful moonlit landscape. The sands of the beach appeared like snow, and the surf in the distance seemed like snow-drift, had it not been for its roaring.

At daybreak I went to the beach and immediately plunged into the waves, to the utter surprise of the by-standers, who assured me that I was the first visitor bathing at Rockaway Beach that year.

As a rule any one free from fever will tolerate the cooling process of a cold bath better if such cooling is preceded by increased warmth of the body, or rather by prevented loss of warmth of body. Notwithstanding that this my first cold bath in open air was by no means preceded by increased warmth of my body, I felt much benefited by it.

During the succeeding summer I bathed daily in one of the popular swimming-schools on the East River, and continued my daily swimming exercise until far into January. I interrupted it only in case the snow happened to be too deep and the path to the steep bank too slippery.

The impression as if I needed an extra stimulus in throwing myself into the ice-cold water soon disappeared. Even during such cold days when I had to rub my ears while on my way to the river, I did not hesitate to bathe. I can safely assert that I felt extremely well in the water.

The only unpleasant sensation I experienced in ice-cold water was a sharp pain of hands and feet, compelling me to leave the water after but a few minutes' swim. In order not to suffer too long, I am in the habit of taking with me from home a bottle containing six ounces of warm water, this is poured upon hands and feet as soon as I escape from the water. This very little quantity is sufficient to promote the well feeling after the cold bath. In fact, the feeling of comfort is extreme; the mind, even if it were depressed, becomes cheerful.

On windy days, if it be not so cold as to cause the wet footprints to freeze while I walk barefooted, I do without a towel, by walking up and down until my skin becomes dry.

My experience does not accord with a well-known rule laid down for bathing in general. A cold river-bath affects me beneficially in case I should be fatigued and tired; after being awake all night, engaged in professional duties, it serves to refresh me mentally and bodily as much or more so than would sleep itself.

The bath is located opposite Blackwell's Island. A boat manned by a guard patrols the river while the prisoners on the island are at work in the quarries. This is toward seven o'clock in the morning, the time I take my bath during the winter months. It often happens that while I am swimming in the water, and this boat is in my vicinity, I converse with the guard. Never, even during extreme cold, did my voice tremble or have I been "out of breath."

As already mentioned, I bathe between six and seven in the morning, even during the shortest days in December, while it is yet dark at that hour.

The increased sensibility, showing itself in shivering and chill in those unaccustomed to cold baths, has entirely left me. During the first years I experienced on extremely cold days, while in the water, a numbness over the surface of the entire body, which remained about one minute. During the past winter I did not have this sensation at all.

As we all know, the tide rises and falls in the East River. At low tide I am compelled to walk through shallow water until I reach a sufficient depth to be able to swim. When still inexperienced I would swim too near the coast, striking my knees or feet on the edges of rocks; but the sensibility of my body was so decreased that I would never feel it until, after leaving the water, I would notice an abrasion or blood.

"Goose-skin" is a condition I never get, either when undressing in the cold air or after the bath.

During the first, and if I recollect rightly, also the second year, I noticed an affection of the spinal cord, namely, a tremor of the lower extremities while dressing, This has left me entirely. Without any trouble I am able to attend to all details of dressing, such as adjusting my necktie.

Once during the second winter I suffered from a cold—pharyngitis and bronchitis.

Large steamers pass up the river, causing large waves to roll in toward the shore. It is a great enjoyment to be tossed about by these. One morning I had just escaped from the water after a bath of the usual duration, about five minutes in cold water, when I noticed a large steamer coming, and in anticipation of another "good swell" I hurried again into the water. It appears that this was too much bathing. Upon going home I failed to notice the beneficial reaction, but, on the contrary, suffered for the next few days from pain on deglutition and a cough which annoyed me day and night—the first and only attack of coughing I have ever had in my life. I had to cease my bathing exercises for the next two weeks.

During the same winter I suffered for a few days with rheumatoid pain in the right shoulder-joint. I had trouble in putting on my coat and overcoat in order to go to the river, and more trouble in taking them off. With the first attempt to swim, all pain left me, and I experienced no difficulty in dressing after the bath. This pain returned several days in succession until it left me entirely. With the exception of the above-mentioned intermission of two weeks, I bathed through the entire winter, also the following one, and the winter of 1889–90; in the latter I had to cease again for about two weeks, having an attack of grip. It will be remembered that the winter was exceedingly mild.

During the first three winters I bathed alone; although there were a number of gentlemen—six, perhaps—who also were enjoying this peculiar winter sport, but they all came at noon. During the past winter I received company—Mr. B., a Hungarian, and Mr. Krug, like myself, a Thuringian. Mr. Krug, who is present, bathed with me throughout the winter, the other gentleman only until January. Both had never bathed in winter in the open air; both were enthusiastic as regards its beneficial influence and the resistance one obtains against the influences of weather. Mr. Krug was formerly very susceptible to cold, inclined to lighter forms of inflammation of the respiratory organs, but has had no such attack this year except once, when he went bathing at an unusual hour and remained unusually long in the water. The result was the same as I had experienced after remaining too long in the water, an uncomfortable, chilly feeling instead of the agreeable reaction, and a rhinitis which lasted for some days. He discontinued swimming for about two weeks.

We had some very cold days—once 16° F.; the coldest day was March 1st, viz., 10° F. One morning the river was entirely covered with floating ice; we were unable to swim, and had to be satisfied with ducking underneath the ice. At one time the path leading to the shore was so covered with ice, that it was with difficulty we got to the bath.

Late in autumn, when the temperature is quite cool, considerable hyperæmia, and even cyanosis, appeared all

over the body while remaining in the water. Especially did this show itself with my comrades, especially Mr. Krug, whose cyanosis appeared sooner and more intensely than with myself. In winter, and hence in a still colder atmosphere, the skin becomes anæmic, but this condition changes into hyperæmia after leaving the water.

During my first year's winter bathing I suffered from an eczema of the lower extremities, accompanied by itching during the night. Mr. Krug suffered from the same inconvenience. An unction of lanolin cured it promptly; otherwise the skin remained intact.

I might mention that the reaction after the bath seems to start from the end of the spinal column; in case of sitting down one has the sensation as if coming in contact with a hot bottle. Seclusion within a warm room half an hour after the bath seemed disagreeable to us.

After the bath the muscular system is refreshed, gaining in elasticity and strength. According to my experience the physiological value and character of the reaction depends upon the incitation of the organic functions; the nerves, the muscular system, and the heart are irritated and react, the increased amount of heat produced and the increased elimination of carbonic acid, that is, an increased combustion of organic elements, is the result of all these reactions. As Jacob and Virchow have observed, a decrease of temperature ushers in the reaction. I must confess that I have not measured my temperature after bathing, but shall do so next winter.

In cases in which there is a certain debility of vital functions, as in children and the aged and anæmic, such reaction naturally does not obtain, and the cooling, the reduction of temperature, predominates.

Liebermeister maintains that some cases of hysteria can only be cured by systematic bathing. A bath is taken daily at the same hour, of fifteen minutes' duration, the temperature of the first bath being at the convenience of the patient; each successive day it is taken one degree less. Exercise is taken out doors or at home after the bath. The temperature of the water is thus gradually decreased to 60° F. If still lowered by the will of the patient, the duration of the bath is proportionately shortened.

This mode of treatment I first adopted in the case of a hysterical American lady in high life. Aside from being a victim of a circumscribed neurosis, for which she had consulted all prominent pathologists in the course of her travels, she suffered from a certain form of hyperæsthesia which one is only accustomed to find among Germans in their native country.

For the benefit of my colleagues who have not lived in Germany, I wish to describe this specific German hyperæsthesia, against which preached and wrote, nearly three hundred years ago, old honest Würtz of Basel. I will name it "'s zieht" ("I feel a draught"). It is laughable when among a crowd of people either within four walls or in a public vehicle somebody pronounces the ominous word "'s zieht." A humorist of the brush would find it a thankful task to depict the effect of this word on the crowd. On some individuals it has the same effect as the word "fire" produces in a filled church or theatre, while others, of more intellectual calibre, express in their faces sarcasm and disgust. The lower classes in Germany invariably call ventilation "zug" ("draught"). Among the educated the enemies of fresh air are rarer. Notwithstanding this fact I heard an American colleague, who had visited the last International Medical Congress, complain how wretched the ventilation had been in those meeting-rooms in Berlin. In a similar strain Professor Preyer, of Jena, complains: "In England, and also in many other countries, the fear of fresh air, wherever many people are gathered together, is hardly known. In Germany this is often manifested to a morbid degree." In German medical journals I often read of "zugigen Räumen" ("draughty rooms") which we would call well-ventilated rooms.

The lady of whom I spoke above had, among other hysterical symptoms, a morbid timidity against any movement of the air, against draught. I ordered Liebermeister's baths, which had a beneficial effect. She seemed to like them, and consequently reduced the temperature far below 60° F. Notwithstanding that she was over fifty years of age, and by no means of robust habit, she lost her sensitiveness to such a degree that she was able to take sea baths late in the fall on days when the water appeared to be too cold to the ordinary bather. The neurosis as well as the hyperæthesia was cured. Instead of shunning draught she exposed herself and seemed to enjoy it.

Although not strictly within the scope of my paper I cannot refrain from saying a few words regarding cold baths as a remedy for diseases in general. The powerful effect of a systematic cold bath in typhoid fever can be well compared with the healing by first intention in aseptic and antiseptic surgery. Liebermeister closed his lecture at the Congress of International Medicine with the following words: "Experience has thus far shown that truly brilliant results in the treatment of serious febrile diseases have been obtained in those cases in which cold baths have been the foundation of therapeutics."

In general it can be said that the cold bath is a true tonic to the heart. It calms the rhythm and elevates the pulse; it corrects the symptoms of weakness, and the weakness itself disappears.

Benecke has shown that baths could be well endured in rheumatism, even if complicated with heart affections. Valvular lesions were cured under their influence within several months after their commencement.

The brothers August and Theodore Schott, in Bad Nauheim, have cultivated a certain method of treating chronic heart diseases by systematic bathing. Their experiences were published in 1880 by August Schott. It is maintained by them that through prudent incitation of the heart the muscular mass of this organ would improve in growth and strength. Under the influence of the bath a continued rapid contraction of the previously dilated heart is obtained, also a strengthening of the pulse and a diminution of all symptoms showing an obstruction of circulation. The aim of all therapeutic action is designated by Schott as a problem to nourish the muscle of the heart, and thereby to increase its hypertrophy and to decrease dilatation.

At the time of my reading the communication of Schott I happened to attend a case confirming the same. An elderly lady had used, of her own accord, without medical advice, sea baths in summer, and during the other seasons cool baths at home, with marked success in bettering her serious complicated heart disease and impeded circulation. It would be quite a thankful task to establish a scientific method of bathing for the pathological conditions of various parts of our system.

In all romantic parts of Europe, more especially in Germany, there are cold-water establishments, and most of them under supervision of scientific physicians. It is to be regretted that almost all we hear of these establishments is confined to advertisement columns.

There can be no doubt that cold baths are a remedy of considerable power, useful or dangerous, as other remedies likewise are, according to indication and mode of using.

Just as much as there exists with some an unwarranted fear against fresh air, there is, in the majority of persons, a dread of cold water. Considerably more than what is done could be accomplished toward the welfare of a great number of patients by gradually strengthening them by the application of cold baths.

The Doctor who was Never in.—"A great many people owe their lives to that doctor," said Kicklington. "Is he an able physician?" "It isn't exactly that I referred to. He is never in his office when you want him."

THE AMŒBA COLI IN DYSENTERY AND LIVER ABSCESS, WITH A NEW CASE.

By GEORGE DOCK, M.D.,

GALVESTON, TEX.

So marked and indubitable are the pathogenic powers of certain of the protozoa that it is rational to seek among those low organisms for clews to the etiological problems that still remain unsolved. The facts now known regarding the occurrence of parasitic amœbæ in man, though not such as to demonstrate their pathogenic nature, are still such as to excite our liveliest curiosity, and the discovery of a new geographical source, opening up a large field of study, cannot be without interest. As previous accounts of the amœba coli are inaccessible to a large proportion of the profession, I think no apology is necessary for the introduction of the following summary.

Aside from an observation by Lambl,[1] amœbæ as parasites of the large intestine were first described by Loesch,[2] in 1873, and named by him amœba coli. The organisms were found in the stools of a patient with chronic dysentery. Improvement in the patient's condition was coincident with the decrease and final disappearance of the parasites from the stools. Loesch injected fæces containing amœbæ into the intestines of four dogs, in three of which there was no effect. In the fourth vomiting and diarrhœa ensued, with speedy recovery, but the stools contained bloody mucus, in which were numbers of amœbæ. The dog was killed on the eighteenth day, and its intestine found inflamed, covered with bloody mucus, and showing three superficial ulcers. In the mucus and in the bottoms of the ulcers were numerous amœbæ. Loesch thought he was justified in assuming that the amœbæ irritate the intestinal mucous membrane, and so hinder the healing of the ulcers.

According to Leuckart, amœbæ were found in the intestine of a child by Sonsino, of Cairo. Grassi and Perroncito [3] found amœbæ in fæces, but attributed no importance to them. The organisms were encountered again in Egypt, by Koch, who found them in sections of the intestines and in stools of dysenteric subjects while carrying on his researches in cholera, in 1883.

In 1885 and the following year [4] Kartulis, of Alexandria, reported his investigations, as the result of which he came to the conclusion that the parasite under consideration is the cause of tropical dysentery. This conclusion was based on the fact that he found the amœbæ in more than one hundred and fifty cases of dysentery, but never in other ulcerative intestinal diseases (enteric fever, tuberculosis), and found them not only in the mucus, but also in the ulcers and deep layers of the intestine in twelve cases in which autopsies were made. In cicatrized dysenteric ulcers the amœbæ were not found. The organisms were similar to those described by Loesch, but differed slightly in size, twelve to thirty micro-millimetres in diameter; Loesch, twenty to thirty-five micro-millimetres. Culture experiments were negative, as were also attempts to infect guinea-pigs and rabbits.

In 1887 Kartulis [5] reported finding amœbæ in dysenteric liver abscess. They were found in sections of the abscess wall, and in one case in the fresh pus. Still later,[6] Kartulis was able to report on a total of more than five hundred cases of dysentery, in all of which he found amœbæ in the stools, but, as before, failed to find them in other diseases. He still held to his opinion of their pathogenic nature, though experiments on monkeys, dogs, rabbits, and guinea-pigs, gave negative results. In this article Kartulis speaks at length of tropical abscess of the liver He distinguishes cases of that disease into two classes—idiopathic and dysenteric, the latter forming fifty-five to sixty per cent. In the idiopathic form various species of pyogenic bacteria were met with. In the dysenteric variety amœbæ were found in all (twenty-two) cases, sometimes accompanied by pyogenic bacteria, and in one case protens vulgaris. Kartulis explains the pathogenesis of the dysenteric liver abscess as follows: "In the ulcers of dysentery the amœbæ often invade all the layers of the gut, and especially the capillaries of the submucosa. From there they wander through the portal vein into the liver, accompanied by detritus, blood-corpuscles, and various micro-organisms. The latter cause suppuration, but only in consequence of the local predisposition set up by the amœbæ, for these, by means of lacerations of blood-vessels, often cause important lesions." That the amœbæ are of great importance in the production of liver abscess is shown by the fact that in Egypt, as elsewhere, typhoid and tuberculous ulcerations of the intestine are seldom complicated by abscess of the liver, and in two cases of intestinal tuberculosis with hepatic abscess Kartulis found only amœbæ in the pus. He claims that the pyogenic microbes die rapidly in the abscesses, whereas the amœbæ remain alive much longer, more than two months.

Histologically, Kartulis distinguishes three zones in the abscess wall. First, the detritus zone, containing fibrin, granules, and amœbæ, seldom bacteria; second, the cell zone, consisting of young cells which stain deeply and between which are broken-down liver tissue, liver cells, and capillaries; third, the boundary zone. Here may be found liver cells compressed together, embryonic vessels, leucocytes, newly formed connective-tissue, and biliary canals. In the vessels are either bacteria or amœbæ.

In a recent communication [1] Kartulis reports the finding of amœbæ in two cases of dysentery in Athens, the organisms resembling in all particulars those studied in Egypt.

An important contribution to the subject is furnished by Massiutin, from the clinic of Professor Loesch in Kief.[2] He found the amœbæ in the stools in five cases. The first was one of chronic dysentery lasting seven years; the second, one of chronic intestinal catarrh, with liquid stools containing small particles of mucus; the third, a convalescent from typhoid fever, with liquid stools and a great deal of mucus; the fourth, acute intestinal catarrh with numerous very mucous stools; the fifth, "chronic intestinal catarrh," with one or two liquid, mucous stools daily. In the first case the amœbæ were very numerous, in the others averaging only one or two in each field. In form and vital characteristics the parasites resembled those described by previous observers, though the individuals varied more in size—six to thirty to thirty-five micro-millimetres.

Massiutin combats Kartulis's view that the amœbæ cause the "bloody diarrhœa, as they are found in other intestinal diseases." He holds that the parasites "reach the intestine with the water, and settle especially in the mucus of the large intestine, provided they find the conditions necessary to their existence." He says, however, that "the intensity of the disease called forth by them depends on the quantity of the amœbæ." "Whether the parasites alone are able, under ordinary circumstances, of producing diarrhœa and intestinal ulcers, even superficial ones, must be left to the future to decide. The experiment of Loesch is not decisive, as he used fæces, not pure cultures." "The presence of ulcerative processes in the intestines seems very favorable for the development of the amœbæ, and the latter appear to keep up the catarrh by their irritative action, and to hinder the healing of the ulcers."

There are evident contradictions in the abstract of Massiutin's article which are difficult to reconcile. Kartulis very properly takes the ground that Massiutin is not justified in assuming that his cases were not all dysenteric because of the absence of certain smyptoms; but it is rather

premature to consider them as dysenteric on account of the presence of the amœbæ. The fact remains that the Russian observer furnishes valuable testimony as to the distribution of the amœbæ.

The first report on the presence of the amœba coli in dysentery in the New World was made by Professor Osler.[1]

The patient was a physician, aged twenty nine, for six years a resident of Panama, where he contracted a chronic dysentery. He came north in May, 1889, went to Germany, and in Vienna had a severe recurrence of his disease. He returned to Baltimore in December. Soon after, an irregular fever began, with occasional chilly sensations, sweats, loss of flesh, and sallow complexion. Signs of abscess of the liver developing, the liver was aspirated, incised, and two large abscess cavities found in the right lobe. In the thick, creamy pus Dr. Osler found amœbæ in large numbers. The organisms could be found in the pus removed at the dressings up to the time of the patient's death, two weeks later. "In this case diarrhœa was a marked feature. Tenesmus was rarely present; the frequency of the stools from four to twelve in twenty-four hours. Their character varied much. Sometimes there were large brownish evacuations with little or no mucus; more frequently three to four ounces were passed at a time, and scattered through the brownish liquid mucus blood and small whitish sloughs could be seen. On several occasions the stools seemed to be made up of a gelatinous mucus streaked with blood, and twice large grayish sloughs were found. The amœbæ were rarely found in the brownish liquid stools. In the mucus they were more frequent, but they were met with in large numbers only in the small grayish fragments, portions no doubt of sloughs which were found in variable numbers in almost every mucoid stool."

Dr. Osler goes on to describe the amœbæ, from which it appears that they resembled those of others, though not reaching the maximum size, measuring in his case ten to twenty micro millimetres in diameter.

Dr. Osler concludes by saying that "it is impossible to speak with certainty of the relation of the organisms to the disease. The subject is worthy of extended study, and a point of especial interest will be the determination of their presence in the endemic dysentery of this country."

The following observation demonstrates the presence of the amœbæ in dysentery in a part of the country where that disease is not uncommon:

R. H——, laborer, aged forty-two, living in Temple, Tex., admitted to St. Mary's Infirmary, Galveston, July 16, 1890. Patient was sick two weeks before admission, with fever and diarrhœa. The stools were at no time carefully examined. While in hospital the patient was in the typhoid state. The stools contained mucus and blood at times, and there were colic and tenesmus. Toward the end consolidation of the lower lobe of the right lung came on, with enlarged area of liver, dulness and pain in the right hypochondrium. Abscess of the liver was suspected. The patient sank rapidly, and died July 25th. By the kindness of Dr. F. Hadra, resident surgeon, to whom I am indebted for notes on the clinical history, I assisted at the autopsy, six hours after death.

There was general peritonitis with sero-fibrinous exudate; inflammation of the mucous membrane of the colon from the cæcum downward, with large, ragged ulcers; liver enlarged, pale yellow, anæmic, the right lobe containing an abscess the size of a head at term. The walls of this were ragged and marked off from the surrounding tissue by a serrated hyperæmic area. The cavity contained pale, dirty-yellow matter, of creamy consistency, and putrid, penetrating odor. There was purulent pneumonia of the right lower lobe. The other organs showed no special microscopic changes. Specimens of purulent matter from the liver and colon were put in clean, dry bottles and removed for examination, but owing to the circumstances under which the autopsy was made no other material could be obtained.

Two hours later I examined the specimens. The matter from the liver contained a few broken-down and macerated leucocytes, and occasionally a red blood-corpuscle. The bulk of it was made up of detritus, cocci, long and thick bacilli, and amœbæ. The latter were present in enormous numbers. With a Zeiss DD objective, and the drop spread as thin as possible, there were never less than three, usually ten to fifteen, in every field. As a rule they were hyaline, or less granular than the ordinary amœbæ, so that without careful examination, or noticing the peculiar motion, their real nature might easily have been overlooked. When round, most of them measured twenty to twenty-five micromillimetres, in diameter; the smallest was thirteen micromillimetres, and one much larger than the rest measured thirty-two micromillimetres. In most the endosarc was very finely granular and pale. All were in constant motion, which, however, varied greatly in rapidity. It consisted in the projection of hyaline lobes at one or more points, and usually resulted in the inclusion of granules. The largest one measured had a coarsely granular endosarc with only a narrow rim of ectosarc. This threw out a long straight pseudopod, and by filling it out and repeating the process made steady progress across the field of vision. Most of the amœbæ had vacuoles in varying number; one had included three red blood-corpuscles, and another a leucocyte.

In the mucus from the intestine the amœbæ were present, but not in such great numbers. They were also more granular than those in the liver, and did not reach such large dimensions. The amœbæ remained active in the respective fluids for more than twenty-four hours, having been demonstrated to some of my colleagues in the meantime.

From what has been said we may safely conclude that the amœbæ coli is a parasite with a world-wide distribution. It is not my purpose at present to discuss the pathology of dysentery or liver abscess, principally because, though I have made some investigations with reference to these parasites, I have no new facts to bring forward. The obstacles in the way of ascertaining the possible action of the amœbæ as exciters of disease are many, and at present insuperable, since we know of no way of isolating them. For some time we may well be content with accumulating facts by microscopic study of the products of disease. Notwithstanding the admirable work done by Kartulis we still need more testimony as to their invariable presence in cases of dysentery, or at least in certain varieties of that disease, and their absence in other diseases. Studies on these lines will lead to an increased knowledge of the natural history of both dysentery and "tropical" abscess of the liver, regarding which an amount of confusion exists which experience shows can only be cleared up by thorough etiological studies.

[1] Johns Hopkins Hospital Bulletin, May, 1890, with a summary of the literature. Centralblatt f. Bakt. u Parasit., 1890, i., No. 23.

From an Amusing Paper on "Our Predecessors, the Barber Surgeons," read by Dr. Embleton before the Newcastle Society of Antiquaries, we learn that the barbers were fined for trimming their customers on the Sabbath-day, and fines were also imposed when members used "ill words" to each other. For "giving" members the "lie" fines respectively of from three to six pence had been made. Were these excellent rules in force nowadays, and if the proceeds were put into a medical poor-box, instituted *ad hoc*, we should have the nucleus of a very useful charity to assist those left destitute by our less fortunate fellows. A rough calculation, based on the number of infractions committed during the last few weeks, shows that several "most potent, grave, and reverend seigniors" would be mulcted in very substantial sums, and one can only regret that no machinery exists for levying this tribute.—*The Hospital Gazette.*

THE UNITY OF DISEASE.

By J. D. PRETTYMAN, M.D.,

MILFORD, DEL.

Every Pathological Process the Result of Malnutrition.—The human body is an aggregation of cells, each one a complete organism, performing every function and carrying out every essential phenomenon of life ; having the power of digestion, expulsion of effete material, interchange of atmospheric gases, absorption of moisture, mobility, etc., all aiding— constituting, indeed—nutrition, and a failure of either resulting in death of the cell. By natural selection every cell contributes force to all of the other cells, and through this co-operation the most intricate and elaborate processes are evolved. Pleasure, pain, every sensation, every emotion, thought itself, is the result of cell activity. Kill the cells, and, according to the extent, you impair and destroy the body. The strength of the part, the health of the body, is as to the vitality of the cells.

By the union of a normal male and female germ element, under natural conditions, man is evolved, and his days are threescore years and ten ; by reason of strength he may attain fourscore. The vitality of spermatozoon or ovum may be so far impaired, through defective nutrition, that in the union they may together perish before maturity ; the germinal vesicle living and developing only as a result of the vitality conferred upon, and contributed by, the primary elements. Every vital process is concerned in the elaboration of the sperm element. It is not merely a testicular or ovarian formation ; it bears the impress of temperament, of brain, of feature ; and these may all be brought to light in its full development and maturity. Vigorous bodies cast off vigorous germs, producing offspring that can cope with the vicissitudes of life and grow stronger with the struggle. The physically weak, badly nourished bodies that cannot perfectly elaborate and sustain the living germs, throw off crippled, sickly cells, and the child resulting from such sexual congress is ready to die at the first rude contact with the world. This, in part, will account for the great infantile mortality ; passing away because the vital force is sufficient to sustain life but a day or a year ; the organization itself defective because the germ from which it was evolved, the seed from which it grew, was defective. A striking illustration is afforded of this in the vegetable kingdom. Seed fall into the ground side by side ; watered by the same clouds, warmed by the sun, under the same conditions and environment, one sprouts and dies, another becomes a shrub, a third is the majestic oak. "As ye sow," no less in the animal kingdom than in the vegetable, "so shall ye also reap."

The impression of the male upon offspring is complete in the elaboration of spermatozoon. He cannot further affect the product of conception. Organization, quality of tissue, cell life, is impressed upon the sperm, and it can only be modified by similar female impress upon the ovum. By tempering differences, the two together form a complete, perfect unity of development. If sperm and ovum have received impress of like organizations that quality of body, of tissue, of cell structure and life, will be brought out and emphasized in the resultant offspring. Beyond this the female has a direct influence upon the development of the fœtus that she is bearing in her womb, nourishing and fitting for a mundane existence. If the vitality of the mother is impaired, if the cells constituting her body cannot together form perfect pabulum, the child may perish in utero, or come into the world with a diminished vitality, already expended in the effort to maintain existence, and less than the original germ-elements would have conferred if developed in a different and more congenial environment. Born with a defective organization the child cannot create pure blood, cannot form food for its own sustenance, and the weakened, almost starved cells have but little power of resistance. Normal blood is Nature's perfect food for the very cells which elaborate it. Without it health and vigor cannot be maintained. It is the life-sustaining, liquid tissue ; and with its modification so will there be also modification in development and extent of cell-life. The physical peculiarities of gens, or family, as manifest in organization and temperament, are as characteristic and distinct as racial differences. It may even extend so far that individual members may be designated by "the mark," the likeness of father or mother. Begotten by healthy, vigorous parents, nourished by pure blood, one family may go on to maturity in ripe old age, while in another the offspring, created with defective organizations, all pass away in infancy or childhood, the result of impaired nutritition in the parent. Derangements of the system that would prove slight in the former bring the latter to the grave—the nutrition of one perfect, the aggregate power of resistance great, while with the other nutrition is only sufficient to maintain life under favorable environment, the power of resistance slight.

Environment may also modify the natural tendency of organization and cell development. Climate may exert a force upon nutrition in changes of temperature, of atmospheric gases, and moisture. Excessive high or low degrees of heat may impair or destroy the body by interfering with the normal blood-supply, the superficial vascular system contracting and forcing the blood from the surface into the viscera, deranging the circulation and consequently the nutrition of the entire body. The cells can best perform their functions at a temperature of 98½° F., and to maintain this the cells of the blood convey oxygen to the carbonaceous elements introduced into the economy as food product, and by chemical union instituted by a vital process the necessary heat is evolved. Nature's provision for the creation and preservation of animal life is through the co-operative work of the cells of the body. Every function, every phenomenon of life is the effect of cell activity ; the life of the cell is, indeed, the life of the body.

Man is the creature of an organization, the resultant of concomitant conditions of germinal development. He cannot escape the predilections and natural tendencies conferred by parent. They may be modified, indeed, by habit and environment, but never wholly overcome. A similarity of tissue, of organic structure, of cell vitality, under the same environment, will develop like physical conditions in offspring as are manifest in parent ; and thus "the iniquity," not acquired habit, but nature, cell vitality, "of the father is visited unto the children ;" heredity being but natural physical conditions of cell evolution. As the germinal cell is impressed with the vitality of the body from which it issued, in like time and manner the offspring may manifest in development the same morbid conditions of parent, the same tendency to death. Malnutrition, the less than normal aggregate cell force, of parent is brought to light in the feeble, sickly, physical conditions arising in the maturity and growth of the child. Length of days is given to the child with a robust organization, that can create from organic substance perfect food for its own sustenance ; pure blood that renews and gives vigor to the cells that they may live out the life, the vital force, imparted by parent. Starved cells cannot live, they can only die. The cells must not only be vigorous themselves, they must also be perfectly sustained. It is perfect nutrition that constitutes health ; impaired nutrition is disease ; a failure of nutrition, death.

Disease is not merely a natural physical condition arising from defective germ-cell evolution. It may be the effect of other internal or wholly external causes ; resulting from any violation of the laws governing development and growth. The blood may become contaminated by introduction into the circulation of foreign elements—a perfect food for the cells, by abnormal changes becoming a poison, preventing nutrition, destroying the cells. Nature is a severe taskmaster and there is no escaping the punishment of physical disobedience. Retribution always comes, and the aching nerve, the throbbing heart,

the weakened muscle reminds us of our failure, protesting against carelessness or excessive indulgence. By an expenditure of vital energy, shortening our days to the same extent, Nature seeks to restore the injured part or organ, until exhausted with the struggle man is no more, physical life is ended, passing away, it may be prematurely, the vital energy used up in efforts at restoration.

A peculiar susceptibility to certain forms of disease may appear in generation after generation, extending to remote ramifications of blood relationship; the "taint" of the parent becoming manifest in the children. Not that specific matter has passed direct from parent, in the process of impregnation, into the germ cell, inoculating the offspring; but that the germ itself, impressed with the vitality of parent, has developed in evolution a similar physical condition, and like causes acting upon like conditions have produced in parent and offspring like results. This is especially marked in tuberculosis, the children of tubercular parents manifesting a decided susceptibility to bacillary influence, while other children may be altogether exempt from the trouble, in the same environment, apparently possessing immunity. It is simply upon the principle of the survival of the fittest that the bacilli tuberculosis overcome the cells of the body, because of greater vitality, power of resistance. The tubercular deposits are dead cells with micro-organisms feeding upon them. Vigorous bodies, whost perfect cells are perfectly sustained, are not subjects of tuberculosis. If such cells are attacked they destroy and cast out the intruding organisms. With these facts in mind the difficulty of successful treatment becomes evident. A constitutional defect, the result of germinal development, cannot be overcome; we can only look to prevention through destroying the exciting cause. With the tubercular process already begun, with the bacilli in the fluids and tissues of the body, we cannot hope for cure upon any other basis than by increasing the bodily strength, the cell activity, by aiding nutrition. The effect of tuberculin and all such poisons is first manifest upon the weakest cells, destroying those whose power of resistance is least. The tissues constituting a nidus for the micro-organisms are first cast off under its influence because the vitality of the cells is already nearly exhausted and consequently they are the least able to resist the poison. The bacilli live on, the cells of the body die—tuberculin thus aiding the bacilli in the work of cell destruction; first killing the body, and then the micro-organisms.

In incipient phthisis only have beneficial effects been claimed for the remedy, and these cases have been selected and specially prepared by favorable hygienic and dietetic measures for the reception of treatment. Under such conditions alone many would have improved and even recovered, the increased nutrition giving strength to the cells and enabling them to overcome and cast out the bacilli. In advanced stages of the disease, where the bodily cells are exhausted, a little of the poison is sufficient to complete the work of destruction already begun and nearly accomplished by the bacilli.

Syphilis, in a measure, is allied with tuberculosis, resulting from the introduction into the economy of a specific virus or microbe, with local and constitutional effects depending upon the physical condition of the subject inoculated. Prognosis cannot be based upon the appearance of the original lesion, for general infection does not always follow the hard, indurated chancre, while it sometimes follows the "soft sore." Fournier's advice is, "Never diagnosticate chancre by the chancre," however characteristic the lesion never pronounce a patient syphilitic until later manifestations appear. There are, then, venereal lesions in every way resembling true Hunterian chancre, the result of inoculation, which the most skilful and experienced diagnosticians cannot differentiate from chancre, that produce no constitutional infection, mere local ulcerations extending by continuity of structure. General infection does not follow syphilitic inoculation in many of the lower animals; they receive and eliminate the poison without deleterious results. Is it not rationa to believe that man, under certain physical conditions, may also possess this immunity, the cells of the body casting out the infection without themselves being overcome and destroyed?

In many cases of undoubted infection the constitutional disturbance is so slight as scarcely to attract attention; a few papules, a mucous patch, a slight sore throat, a little alopecia, and without treatment the symptoms disappear never again to return. "Self-limited," we are told, but why? It is precisely the same infection that assumes in others a most virulent form; with every organ, every tissue involved. Ulcerated throat, phagedenic skin, gummatous muscles, necrosed bones—man becoming loathsome and disgusting in his rottenness. As in diphtheria, scarlet fever, small-pox, and other forms of disease, so in syphilis, one subjected to infection escapes altogether; a second manifests slight general effects; a third passes away; the deleterious effects being inversely to the vitality of the body, the purity of the blood, the nutrition of the cells.

Bright's disease is not simply a result of morbid changes occurring in the kidneys; the entire vascular system is involved, with the primary lesion in the sympathetic ganglia, the governor of the circulatory apparatus. The languid heart, the capillary changes of retina, the infiltrated tissues indicate the condition no less plainly than the nephritis. The nutrition of every structure is, indeed, involved, and it is no more a nephritis than a hepatitis, a bronchitis, or a pneumonitis; the quality and amount of blood-supply affecting every organ and function of the body. It is probably the result of cell-failure in the elimination of effete material. In December, 1890, a gentleman came to me, weak and languid, with general nutritive changes apparent, having been reduced in flesh during six months from one hundred and fifty to one hundred and fourteen pounds. Upon examining his urine I several times found slight traces of albumin with a few casts. He passed from my care, after three weeks of treatment, into the hands of a celebrated physician of one of our Eastern cities. Without even asking for a specimen of urine the physician pronounced the trouble bronchitis; and he was correct, at least as correct as I in calling it nephritis, for neither term designated the true condition. The man had bronchitis, he had nephritis, but he had also something more. They were but symptoms of a general condition, and should have been so regarded and treated. The great error toward which the profession is drifting is specific medication—a remedy for every symptom regardless of the cause. We cannot hope for cure in Bright's disease while all treatment is directed to the kidneys in the administration of diuretics. The morbid change in these organs is not the cause, but the result, of the condition.

Pneumonia is generally attributed to causes arising external to the body; but with two persons subjected to the same environment one develops the disease and the other escapes. There is a predisposing cause in the former that is not present in the latter, for otherwise in both would arise the same morbid condition. It is, usually, in plethoric subjects that such severe forms of inflammation arise; those in whom excretion is not relative to ingestion, the body becoming contaminated with its own excreta and the blood poisoning rather than properly nourishing the cells. With nutrition properly maintained a pathological condition cannot arise; there can be neither anæmia nor hyperæmia; neither atrophy nor hypertrophy. Perfect nutrition means perfect health to the exclusion of disease.

Milford, Del.

Professor von Helmholtz. — President Carnot, of France, has conferred the Grand Officer's Cross of the Legion of Honor on Professor von Helmholtz. It is said that this is the first French decoration conferred upon a German since 1870.

NOTE ON THE INTERNAL USE OF WATER IN THE TREATMENT OF TYPHOID FEVER.

By BEVERLEY ROBINSON M.D.,

NEW YORK.

Despite the objections of many to the systematic use of cold baths in the treatment of typhoid fever, according to the method of Brand, this system has, with little reason to doubt it, accomplished a remarkable number of cures. I was one of those who was loath to believe the evidence in its favor, and this inability on my part to accept what seemed absolute proof to many prominent clinicians was due to the fact that it looked to me, notwithstanding the force of its advocacy, too much as the plea for a specific treatment, suitable and adapted to all cases, under all conditions. Again, I was opposed to the use of these cold baths because I believed I saw harm in them. I thought I could recognize a weak heart made weaker, respiration more rapid and irregular, a nervous system unduly and roughly impressioned, and the entire economy subjected to an unnecessary and seemingly brutal assault to satisfy the exaggerated convictions of a few too enthusiastic observers. I have in a measure changed some of my impressions of a year, or more, since. I have been seeking, however, for a different and more satisfactory explanation than the one which has been received for the manifest utility of cold baths in typhoid fever, and I have likewise sought to discover a less objectionable manner of employing cold water than by immersing a poor sufferer during several weeks, day and night, whenever the temperature reaches 103° F. in the rectum, into a bath of 65° F. Both the explanation and the method have come to me through the experience of Debove, Meigs, Beaumetz, and Cantani. To the former I feel especially indebted, since it was only after reading his remarks before the Medical Society of the Paris Hospitals, on July 25, 1890, following the report of Mr. Merklen as member of a committee appointed by this society to investigate the treatment and mortality of typhoid fever in the Paris hospitals, that I determined to make use of water, given internally, in its treatment. With the exception of Dr. Debove the committee generally accepted the treatment of typhoid fever by means of cold baths and following Brand's method, as the best we had, in view of the very small percentage of deaths which occurred after its use. Dr. Debove alone took exception to the Brand treatment and said that he had treated one hundred and fifty cases of typhoid fever by means of cold water given internally, and that his percentage of deaths was quite as low as that given by Brand and had the advantage of not obliging his patients to undergo a very painful medication. Dr. Debove prescribes no drugs, but he urges his patients to drink water. He gives them six to seven litres in twenty-four hours. Each patient passes his urine into a vessel where it is kept, and if the quantity does not seem sufficient to Dr. Debove he stimulates the zeal of the nurses and, as he says, he does not simply allow his patients to drink, he obliges them to drink. Dr. Debove concludes that many complications in typhoid fever—if not, indeed, all—are the effect of a poison, and the way of elimination of this poison is is through the kidneys. If cold baths act, perhaps they act in promoting diuresis, for this diuresis is noticed by almost all clinicians. Certainly, to my mind, this is a more rational explanation of their usefulness than to say that they are mainly serviceable on account of their antipyretic effects. No doubt the explanation given by Brand himself, and reaffirmed by many foreign observers and by Dr. Baruch in New York, that the beneficial effects of the baths consist mainly in the fact that they restore nervous tone to the general system, and thus favorably modify many secondary symptoms which evidently are closely allied with a lowered condition of the nervous centres, is still in part correct. At the present time, however, in view of some researches that have been made in Europe and reported in our medical periodicals, I am also inclined to the belief that increased diuresis should be obtained in order to promote recovery in typhoid fever cases. A review, indeed, of the histories in which the cold bath treatment is reported, shows that one of the results secured by the method is an augmented urinary secretion. Whether or no, with the increased bulk of the urine there is also a large elimination of sold excrementitious substances I cannot say positively, nor do I believe, until lately, that any exact experiments have been made in regard to this matter. What has now been definitely ascertained is that by the use of antipyretic drugs, such as antipyrine, antifebrin, phenacetin, etc., the specific gravity of the urine is increased during the time they are taken and less uric acid is excreted by the kidneys. The contrary seems to be true of those cases in which the cold baths have been steadily given. Many years ago Meigs [1] made some observations in order to find out, if possible, the quantity of water required by a patient suffering from an acute febrile disorder. In order to accomplish his purpose he had the fluid taken in twenty-four hours by four patients accurately estimated. The first case was one of mild typhoid in a woman sixty years of age. During twenty-one days of the fever the daily average of liquid food consisted of twenty-one ounces of milk, and eleven ounces of beef-tea. About twenty ounces of free water and a little over three ounces of brandy were also taken, making in all fifty-five ounces of fluid for each day. The patient recovered. In the second case of typhoid fever the patient took daily, during fourteen days, sixty ounces of free water, and during four days thirty ounces of water daily. In addition he took each day four pints of milk and one of beef-tea, making the total average of one hundred and thirty three ounces, or eight pints and five ounces. In the third case the average daily amount of free water was fifty-three ounces and added to this four pints of milk and one of beef-tea—total daily average of fluid was one hundred and thirty-three ounces, the same precisely as in the second case.

These cases show very clearly, as Meigs states, the proportion which thirst bears to the heat of the body, for the water taken in the mild case (the first one) was very moderate in amount. In the other two cases the thirst was incessant and the water taken large. The supply of food, also, was much greater in the severe cases, as the waste of the body, by internal combustion, was excessive. Professor Cantani,[2] in his treatment of typhoid fever, considers the slight reductions of temperature obtained by drinking cold water as preferable to the marked antipyresis obtained by a cold bath. He adjoins to cold water by the mouth large injections of cold water, rendered slightly antiseptic, by the rectum. The latter he administers twice daily.

Both of these methods of treatment increase the quantity of urine and diminish its specific gravity, especially the drinking of water, and, as Cantani believes, the antithermic effect is produced more surely than by other hydro-therapeutic methods. It likewise seems evident that the cold water is absorbed in large quantities and then cools the entire body and even the blood. In this manner Cantani considers that the tissues are permeated and cleansed by the water and freed of ptomaines, and this takes place without disturbance of any kind, except occasionally a slight chill. Cantani also believes that if cold injections be employed at the beginning of typhoid fever it is possible to abort the disease in very many cases.

Beaumetz regards the promotion of abundant diuresis as one of the elements of success which ought always predominantly to enter into our therapeutics of typhoid fever. He believes that it is useful to favor as much as possible the elimination of the products of organic disintegration. With this object in view it is necessary to give our patients abundant drinks to favor diuresis.

[1] On the Internal Use of Water for the Sick. Philadelphia, 1850.
[2] The Dietetic Gazette, May, 1891.

As Dr. A. H. Smith,[1] in another and very different connection, says so wisely, we are apt in these cases to give freely of albuminous substances, and too often the instinctive craving for simple water to dilute the blood and facilitate its passage through the lungs is met by the constant proffer of milk, beef-tea, etc., in which the water is spoiled for nature's purpose by the addition of unnecessary food. He would have added, doubtless, in typhoid cases that the craving for simple water is to wash out the kidneys, and thus prevent intoxication from retention of the waste of nitrogenous tissues, and to evaporate from the lungs and skin, and thus regulate the abnormal temperature of the body.

On taking charge of my hospital wards at St. Luke's last autumn, I determined to treat my typhoid cases, tentatively at least, with cold water internally. Subsequently this treatment was carefully employed in three cases, apparently of moderate severity. These cases all did well. There was scarcely an untoward symptom. I experienced no difficulty in giving each of them four to six ounces of water every two hours in addition to the three or four pints of milk, that they were taking daily. This amount of fluid caused no disturbance whatever, not even a slight dyspeptic attack, and the patients took it without a murmur. The amount of urine was notably increased in each case and its specific gravity lowered, as I had a right to infer.

These patients gradually recovered their strength and health, and the convalescent period continued most satisfactorily. In a fourth case, begun after this method, I felt obliged to supplement the internal use of cold water by cold baths after Brand's method. This case was one of particular severity. He ultimately recovered, and, so far as I could determine, was benefited by the cold baths. In making the foregoing plea for the internal use of water in treating typhoid patients I do so in the belief that we will thus be carrying out nature's prescription. I do not say that it will prove as efficacious as the method of Brand, but I am hopeful that it may. At all events, it may properly supplement it, and it will have two very great advantages, *i.e.*, it can cause no harm, and is perfectly simple and easy of trial.

Clinical Department.

A RARE COMPLICATION OF LABOR.

By W. H. JOHNSTON, M.D.,

BIRMINGHAM, ALA.

Mrs. L——, aged thirty-nine, has been married for more than twenty years; never pregnant before this time. I was called to see her at 11 P.M. Tuesday, May 20th. She was having pains every three to five minutes, and told me she had pains Monday night and all day Tuesday. Upon examination I found the head at the inferior strait, and with two fingers in vagina I could not feel any os uteri. She was very sensitive, and the perineum was somewhat rigid. I left an opiate to be taken if pains became severe, and told them to call me if necessary. I saw her again at 8.30 A.M. Wednesday, and still was unable to find any os uteri on examination. She did not take the opiate, and had slept none during the night. I then gave her fifteen grains of chloral every hour until sleep came, or three doses had been taken.

I believed the os uteri was in the hollow of the sacrum and I could not reach it with two fingers. I saw the patient again at 12 M. She had slept about one hour and a half, and was perfectly comfortable between the pains. The examination revealed no change. Saw her again at 6 P.M, and was informed that water had been dribbling from her. Her pulse had gone up to 120 per minute. I then anæsthetized her, introduced my whole hand into the vagina and examined carefully, and could not find any os uteri. At one point on the anterior wall of the uterus I discovered a slight indentation not larger than an English pea. I got Hanks' hard rubber dilator and after some difficulty succeeded in passing it in there and to the side of the head, and then I introduced my index finger and stretched as much as I could with it, then two fingers, and dilated with them until the os was considerably larger than a silver dollar. The pains continued, and after five hours the os was not quite as large as the opening of a teacup and no caput succedaneum had formed. Pulse 120 and patient restless. I then determined to terminate the labor. My friend, Dr. Sholl, came to my assistance and concurred in my opinion and anæsthetized the patient. I applied the forceps and finished the dilatation of the os with them. Imitating nature as nearly as possible I succeeded in delivering the child in forty-five minutes without any laceration of cervix uteri or perineum. The child was alive and all right. On Thursday morning the bladder had to be catheterized and again in the afternoon. Pulse 110; no fever. Friday morning pulse normal and bladder acting.

This patient stated she had always suffered with cramps at her menstrual periods. She had been treated in New York City some years since for eight months by a prominent gynecologist, but was not relieved, and she was afterward examined by another physician, who is eminent in the profession, and he told her she would never have a baby.

Why did not the os uteri dilate? There was no cicatricial tissue around the os, and to the touch it was precisely like that of the anterior wall of the uterus. There was not entire obliteration of the os or closure, or else the waters could not have dribbled away as they did.

This patient suffered with intense nausea during her pregnancy, and at one time I thought it would be necessary to induce abortion, but fortunately a change for the better took place, and she managed to get along fairly well.

I have never seen or read of a similar case.

A CURIOUS CASE OF VISION DEPENDENT ON THE USE OF BOTH EYES.

By T. F. BLISS, M.D.,

SPRINGFIELD, O.

Edna S——, a bright girl, eight years of age, came to my office December 15, 1890, for an examination of her eyes. She had been in school two years, and during that time had made frequent complaint of poor vision, but little attention had been paid to it. By referring to my notes of an examination of the eyes of thirty-seven hundred children in the public schools of this city, two years ago, I found that I had reported her as having convergent strabismus and hyperopia. At this time there was no apparent strabismus, but her eyes had a staring look and a general choreic tendency and restlessness.

I seated her fifteen feet from Snellen's test-card and began the usual test for vision. As she did not read $\frac{15}{200}$ with the left eye, I sent her toward the card and made my first record, V., L. E. $= \frac{1}{200}$. Seating her again I went through the usual routine with lenses, without finding one that gave any positive improvement in vision.

I repeated the process with the right eye, making a very thorough test, but with no better result than before; during the trial, by going to the card, she had learned the names of some of the largest letters, and would appear to see one when across the room, with some lens, and call it right, but the next minute could not verify the answer. I then took off the glasses and she read "minion" type with both eyes, at six inches, but did not make a single correct answer at fifteen feet, with or without lenses of any kind, and the only record I could make of binocular vision was $\frac{3}{200}$, for distance. I prescribed atropia, gr. iv.; aquæ, $\frac{5}{5}$ j., to be used in the eyes twice a day, and she returned two days later for another trial.

With the ophthalmoscope the fundus appeared normal and both eyes indicated a hyperopia of two dioptries. With the test lenses, however, I was unable to get any better vision than before in either eye; beyond a few correct guesses, she admitted that she saw "only scratches" on the wall. Ignoring all other tests I decided to trust the ophthalmoscope, and put on a pair of glasses of + 2 D., for her to wear a few weeks, hoping for some improvement in vision when the effect of the atropia had passed off. To my surprrse she began reading the larger of the test letters, and after several changes I was able to record V. = $\frac{1}{4}\frac{5}{0}$ with + 1.50 D. lenses. With these glasses on, however, if I covered one eye the other was as helpless as before. She has worn them seven weeks, and during this time I have seen her four times, and, without further details, give this statement as the result of my completed examination. Vision, R. E. = $\frac{1}{2}\frac{1}{0}$. Counts fingers in a space one foot in diameter, on temporal side at fifteen feet. The remaining field of vision is dark, cannot distinguish colors, and at night, by gaslight, even this amount of vision is reduced, as she only has a light-spot as a field of vision, and can only count fingers two feet away. The record for the left eye is exactly the same in detail and need not be repeated. Neither eye was improved by any lens tried. When both eyes were tested together, no definite result was reached until the accommodation was relaxed by atropia, when we found binocular vision = $\frac{1}{4}\frac{5}{0}$ with + 1.50 D. lenses, now improved to $1\frac{5}{8}$ for distance, and she reads diamond print without trouble. This is her best vision. If the strength of either lens is changed, she recognizes it at once, and one dioptry plus or minus will shut off sight from one eye, and make the other as helpless as before. There has been a decided improvement in her nervous symptoms since wearing the glasses, and she has attended school without complaint.

In this case atropia and the ophthalmoscope give us a diagnosis of simple hypermetropia, this, when corrected with the proper lenses, gives normal vision and all the conditions of a perfect eye.

A systematic examination of each eye by objective tests and lenses gives amaurosis, temporal hemiopia, contracted field of vision, color blindness, nyctalopia, and low vision in both eyes. I am aware of the fact that a squinting eye may suppress the image, and become as helpless as this, but have never seen two such eyes in company with normal vision between them, and do not recall a report of a similar case; and I find myself asking what compensating relation do these eyes hold to each other that they are so helpless alone, and so perfect together? If she cannot see with either eye, how can she see with both? Where is the latent power that transforms two limited fields of vision, with no idea of color, to an open field, with a perfect color sense? Is the fact of the disappearance of the strabismus of two years ago any evidence that binocular vision is sometimes a necessity to give correct sight, and if so, why has not this fact been made prominent in the teachings and writings of our leading authors, as an exception to the general rule in the systematic examination of the eye for defects of vision?

I have made this report as brief as possible, leaving out details of methods and proofs used to verify the correctness of the examination, and believe that under the rigid tests used any material deception would have been impossible, and submit it to your readers as rare, if not unique.

Three Outbreaks of Rabies have been reported to the State Board of Health in Minnesota lately, one in which the disease was supposed to have affected a cow, and two where dogs were the suspected subjects. The Secretary of the State Board investigated the cases, proving the non existence of the disease in the cow by examining its brain, and in the case of the dogs making inoculation experiments upon rabbits with emulsions of the spinal cords.

TWO CASES OF HOMONYMOUS HEMIANOPSIA.

By GEORGE J. PRESTON, M.D.,

PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

The following cases of hemianopsia, occurring in my service at the City Hospital, present some points of interest, especially as one of the cases furnished an autopsy confirming the diagnosis.

Case I.—John W. W——, aged fifty-one, laborer. Family and personal history good. About two years before admission into hospital he began to suffer from headache and attacks of vertigo. The headache was at that time only of moderate severity and was usually felt in the frontal region. He says he had occasional attacks of vomiting, though this was by no means a prominent symptom, and may have been simply coincident, as it was elicited by questioning. He complained of some rigidity of the muscles of the neck, and said that at times his head would be thrown violently backward. No attacks of this kind ever occurred during the time he was under my observation. All reflexes were normal and there was no paralysis of either motion or sensation. He complained of some pain in his head, usually rather more frontal than elsewhere, with an area slightly sensitive to moderate percussion with the fingers, in the occipital region and to the left of the protuberance. He said that he thought there was some trouble with his eyes, which proved to be complete right homonymous hemianopsia. The ophthalmoscopic examination made by Dr. Harry Friedenwald showed double optic neuritis; margins of papillæ very much blurred; papillæ pink and very hyperæmic. Arteries somewhat narrowed, veins not much altered but slightly tortuous; background otherwise normal. The patient was a robust, well-nourished man, and was not much incommoded by the few symptoms that have been mentioned. The diagnosis of tumor of the left cuneus was made. The patient was put upon increasing doses of iodide of potassium, with no good results, and then operation was advised. The patient died suddenly, apparently from pressure upon the medulla. The autopsy, made by Dr. Keirle, showed a tumor involving the whole of the cuneus of the left occipital region, and encroaching somewhat upon the precuneus. The tumor involved all of the cortex of the occipital lobe as far as, and probably including, the angular gyrus. It was difficult to decide whether this latter convolution was included in the growth or not, as all the convolutions of the occipital lobe were pressed out of shape. There was no other lesion. Microscopic examination of the tumor showed it to be a spindle-cell sarcoma, originating in the sheaths of the vessels.

Case II.—John C——, aged forty-seven, blacksmith; specific history, marked arterio-sclerosis. About two years ago, while in good health, he had a moderately severe headache for a day or two, perhaps longer, and suddenly became aware that his sight was in some way affected. He had no loss of consciousness or paralysis. Had attacks of vertigo, and complained of stiffness of his neck. Headache does not trouble him at present, though he occasionally complains of it. Has no local tenderness to percussion of head. Reflexes normal. No vomiting. Says he would be all right if he could only see properly. Has complete right homonymous hemianopsia. Ophthalmoscopic examination, made by Dr. Harry Friedenwald, showed pale disks, arteries and veins narrow. Vision in both eyes, $\frac{1}{4}$. From the history of the case, the condition of the arteries, which were markedly sclerosed, and from the fact that there was no optic neuritis or involvement of either motion, sensation, or cranial nerves other than the optic, the diagnosis of embolism of the left posterior cerebral artery was made. The patient is still under observation.

In the first case the interesting feature was the possibility of relief by an operation. At the time the patient

came under observation, which was only a few weeks before his death, the tumor, as shown by the autopsy, was too large for operation. It might have been possible to have removed it, but it was in a difficult position to reach, and it involved such a large amount of brain substance that the hemorrhage would have been difficult to control. Still it might have been removed. Had an operation been done a year before the patient was seen by me, or, say a year or less after the tumor began to grow, the removal of it would not have been very difficult, as it was probably loosely attached at that time, and small enough to be completely extirpated. The thing that surprised me most in the case was the very few symptoms excited by a tumor involving the greater part of one occipital lobe. The man's mental condition was perfectly good, in fact he had no troublesome symptoms but the visual defect. Both the cases, provided the diagnosis is correct in the second case, go to confirm Wilbrand's observation that the pupil reflex is not interfered with when the lesion is in the occipital cortex or caudad of the corpora quadrigemina.

Progress of Medical Science.

The Nutritive Value of Rectal Injections of Egg Albumin.—The assertions of Voit and Bauer and Eichhorst. to the effect that egg albumin is absorbed by the rectum only in the presence of a certain proportion of chloride of sodium, but is returned unaltered with the fæces if this reagent be absent, has led the author to investigate this point anew, and to make his observations on man, and not on dogs, as his predecessors had done. The experiments were planned with great care, and the quantity of albumin removed from the body, both by the urine and the fæces, was estimated. As the outcome of several series of experiments, the results of which show a great agreement, Huber gives as his conclusion that egg albumin simply beaten up is absorbed by the rectum, but only in very small quantities, and consequently a nutrient enema of this kind possesses hardly any value. When, however, a certain amount of common salt is added (fifteen grains to each egg in the present series of experiments), the quantity of albumin absorbed is doubled. Peptonized egg albumin was absorbed in very slightly greater proportion than that treated with common salt. Of the albumin thus treated with salt, between sixty and seventy per cent. was absorbed, and we, therefore, have in this mixture an extremely valuable material for nutrient enemata. In no case of Huber's were the enemata expelled; nor was albuminuria ever found to occur after their use. —*Medical Chronicle.*

Hydrastis Canadensis.—From a physiological and therapeutic study of hydrastis Dr. Cerna (*The Therapeutic Gazette*) has arrived at the following conclusions: 1. Hydrastine is poisonous to both cold- and warm-blooded animals. 2. The minimum fatal dose of the drug in the common frog (*R. esculenta*) is 0.001 gramme for every thirty grammes of the animal's weight. 3. The minimum fatal dose of the alkaloid in the dog, by hypodermic injection, is 0.50 gramme for every kilogramme of the body-weight. 4. Hydrastine destroys the irritability of the muscular tissue. 5. The alkaloid likewise destroys the excitability of the efferent or motor nerves. 6. Very large quantities produce loss of the functional activity of the efferent or sensory nerve-fibres, and also cause anæsthesia when locally applied. 7. Hydrastine, in small amounts. increases reflex activity by stimulating the spinal cord. 8. Later in the poisoning, by large quantities, hydrastine diminishes reflex action by stimulating at first Setschenow's centre in the medulla oblongata, and afterward abolishes it by paralyzing the spinal cord. 9. The paralysis produced by the drug is due to an action upon the muscles, the motor nerves, and spinal cord. 10. The convulsions of hydrastine are of a spinal origin. 11. Hydrastine destroys the electro-excitability of the cardiac muscle. 12. The alkaloid, in small doses, produces a primary frequency in the pulse-rate, due probably to a stimulating action on the cardiac motor ganglia. 13. In moderate and poisonous amounts it diminishes the number and increases the size of the cardiac beats by an action upon the intracardiac ganglia and the heart-muscle itself. 14. Hydrastine lowers arterial pressure by a direct action on the heart, and also through a paralyzing influence exercised upon the centric vasomotor system. 15. The drug produces at first an increase, and afterward a decrease, in the number of the respiratory movements. 16. Hydrastine kills by failure of the respiration.. 17. The alkaloid lowers bodily temperature. 18. The drug increases peristalsis. 19. In hydrastine-poisoning the salivary and the biliary secretions are largely increased, especially the latter. 20. Hydrastine locally applied produces at first contraction of the pupil; afterward dilatation of the same.

Dangers of Sulphonal.—Although sulphonal is probably one of the safest, as it is one of the most efficacious, among the hypnotics recently introduced, the series of cases published by Bresslauer, of Vienna, show clearly that it has certain dangers. The degree of peril is difficult to estimate, as the patients were lunatics, and were also apparently feeble; but the fact is significant, that out of seventy-seven patients who were treated with the drug, no less than seven showed serious symptoms, and in five of these there was a fatal termination. It ought to be mentioned that the patients had been taking the drug for a considerable time in good doses, and had borne it well until symptoms of disturbance set in, these being great constipation, dark-brown urine, slow, or in some cases rapid but feeble, pulse, discolored patches resembling purpura on the limbs, and great prostration. In the cases which ended fatally, the cause of death was heart-failure, with œdema of the lungs.—*The Lancet.*

Interlobar Pleurisy.—Professor Potain has published a paper dealing with the subject of interlobar pleuritic effusion. A typical case is recorded where pus is periodically evacuated through the bronchi, and in which there are evident signs of fluid effusion in front of the upper lobe of the left lung, but not in the general pleural cavity, the fluid being probably localized by firm adhesions. The diagnosis of such cases is always difficult, and a localized collection of fluid may frequently be mistaken for a solid mass unless due precautions are taken. They commonly occur as interlobar effusions, or as effusions between the lung and the diaphragm. In either case they are almost always purulent. The occurrence of frequent rigors and a dry cough, if not due to congestion or accompanied by signs of a general pleurisy, should always suggest the possibility of interlobar effusion. Physical signs may not at first be present, but show themselves as the fluid approaches the surface. It is usually evacuated through the bronchi, setting up a certain amount of irritative bronchitis in the process. The opening into the lung is usually small and irregular, and it is rare for air to escape from the lung into the abscess cavity. In cases where such escape does take place, it generally happens that putrefactive changes are set up in the fluid which remains behind, and this necessitates an operation to evacuate and disinfect the cavity. In cases such as the one related, where there is no evidence of change taking place in the pent up fluid, no operative measures are proposed. Unlike a general empyema, the interlobar form shows a marked tendency to spontaneous cure.—*L'Union Médicale.*

Treatment of Pneumonia with Large Doses of Digitalis.—Dr. Petresco, of Bucharest, makes an infusion of sixty grains of powdered digitalis leaves to six ounces of water, a little syrup of orange being added to sweeten it. A

tablespoonful of this mixture is given every half-hour. In spite of the largeness of the dose, he says he has never met with a case of poisoning, and maintains that these doses are therapeutic, and not toxic. The best results are obtained in fibrinous or croupous pneumonia. The author states that if used in the way he describes, digitalis will frequently cut short an attack of true croupous pneumonia. In from twenty-four to forty eight hours after taking the drug, a certain fall of temperature occurred, from 104° F. to 98° F.; this being accompanied by a decrease in the frequency of the pulse and respiration. The digestive tract was little affected. The most marked changes were noticed in the pulse. which became slow, full, and of high tension. The conclusions to which Petresco has come are as follows :

1. When given in therapeutic doses, digitalis has a direct antiphlogistic action. 2. The dose may be raised as high as from 60 to 120 grains of the leaves given as an infusion within twenty-four hours. 3. This treatment may be continued for from two to four days, if the severity of the case requires it. 4. When improvement takes place in the circulation and respiration, this is speedily followed by a disappearance of all local signs and symptoms. 5. The success of this treatment is confirmed by the statistics. In an elaborate table of statistics Professor Petresco shows the superiority of digitalis over the other methods. Thus the highest mortality in pneumonia (34.5 per cent.) occurred when bleeding was practised, and the lowest (three per cent.) when tonics, alcohol, etc., were employed. When digitalis, however, was administered the mortality sank as low as 2.06 per cent. 6. From an experience of a very great number of cases, both of his own and other medical men, he maintains the doses, as given above, are perfectly harmless. 7. After a comparison of the various methods of treating pneumonia, Petresco affirms that the expectant plan is not only without reasonable foundation, but even dangerous. His experience has demonstrated that an attack of pneumonia may be aborted if the treatment is commenced at the earliest stages of the disease.—*Therapeutische Monatshefte.*

Piperazin.—This substance is said to have the property of dissolving a large proportion of uric acid. One part of the urate of this substance is soluble in about fifty parts of water. Urate of lithia requires three hundred and sixty-eight parts of water to dissolve it; the piperazin salt is, therefore, seven times more soluble than the lithia salt. Piperazin is not toxic and not caustic, and it appears to have advantages over other substances which may be used to act as solvents for uric acid.—*Berliner klinische Wochenschrift.*

Ununited Fractures.—Dr. Sommer has collected from the records of the Zurich Klinik, 16 cases of ununited fractures. The time was from April 1, 1881, to January 1, 1888. Six cases occurred while the patients were under treatment at the hospital for recent injuries. These were from 489 cases of fresh fractures, among which were also 16 cases of delayed union where comminution, necrosis, and suppuration were the causes. The remaining 8 cases were admitted for already established pseudo-arthrosis. The site of the lesion occurred twice in the shaft of the femur, four times in the tibia, three times in the humerus, twice in the forearm, and three times in the radius. Three patients were women, and eleven men. Ages sixteen to seventy years. Etiology : Not from constitutional conditions except, perhaps, in one case of anæmia from excessive hemorrhage combined with severe diarrhœa. The local conditions seemed to be more important causes of non-union : very oblique fractures with tendency to displacement, permanent interposition between fragments of soft parts, insufficient fixation of fragments, etc. The cases which were to be ununited fractures always showed no tendency to union, never merely a yielding of fragment. The results showed great impairment of function. Callus formation was entirely absent in nine; in the other five a mass of connective tissue united the fragments. The duration of these cases from time of injury to treatment was as follows : six within six months; seven, from seven to eleven and one-quarter months; one, two and one-half years. At the operation, isolated cicatrized ends of fragments were found in eight cases; in three others, a fibrous union of fragments. No case of neärthrosis was reported. Mechanical treatment was unsuccessful except in one case, and here the substance between the fragments was subcutaneously ruptured. The operative treatment : In two cases, nails in the connective tissue band of union (Malgaigne); once, no reaction; once, slight fever, marked local pain, subsequent consolidation; in four cases, the Diefferbach method, with the modification of cutting off the ivory pegs at the surface of the bone and leaving them permanently *in situ* (Bidder); resection of ends of fragments in eight cases; six times with silver wire suture. Seven successful results. One case remained unhealed and refused a second operation. In one case, a femur, the upper fragment was cut wedge-shaped, and inserted in the central cavity of the lower. Munk reports the successful treatment of five cases (one a fresh compound fracture, four cases of pseudo-arthrosis), by ivory plugs placed in the medullary canals—one humerus, one femur, and three tibiæ. Three were discharged with firm union; two with union, but still under observation at time of publication. He attributes the result to the fixation of the fragments by the plug, and to the production of osteoplastic inflammation by its presence. The method seems to him to be especially valuable where there is a separation of fragment ends by loss from comminution or other causes, the plug then forming a firm bridge and being the nucleus for callus formation. This fixation is valuable in fresh oblique fractures of the leg. Munk exposes the ends of the fragments, and then fits the ivory plug into the canal, which is previously bored out, if necessary, to admit it. The technique by which the ivory plug is prepared or sterilized is not stated, but the aseptic healing of the wound is considered of vital importance. The plug is not absorbed, but remains indefinitely.—*The Boston Medical and Surgical Journal.*

Intestinal Concretions and Calculi.—In connection with a recent case of the kind published in the *Provincial Medical Journal*, Dr. Reeves writes as follows : Multiple intestinal concretions and enteroliths seem difficult to explain in the present state of our knowledge, unless we assume that the patient must have passed biliary sand, gravel, and small gallstones into the duodenum at various times, and that these became the nuclei of the intestinal calculi, the outer layers of which were formed by deposit from the intestinal walls and contents at different times and at different periods. Intestinal stones are usually single, and when multiple are commonly facetted, though in my case there was scarcely an attempt at this, showing that the calculi were formed independently, and only became related to each other in the sigmoid or upper part of rectum. On removal they were moist, and weighed considerably more than they did a few days after, when the watery part had evaporated. On section—only two or three were cut—there was an attempt at a concentric arrangement, though a radiated appearance from the centre to the periphery predominated. No chemical examination was made, and a microscopical examination of the outer layers showed a felt-like matting of indefinite structure, held together by inspissated intestinal mucus. The average size of these stones was that of an ordinary English walnut, though several were smaller, and two or three larger, the largest being the size of a Tangerine orange. They numbered forty-seven, and a few of them were more or less polished, and in these there was an attempt at facetting, so that both were most probably caused by their probable presence in the centre of the quarry, and by the attrition due to peristaltic motion. Some of them appeared to be more or less porous.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

AN INDICTMENT OF CORROSIVE SUBLIMATE AS A DISINFECTANT.

IN an article entitled "Corrosive Sublimate as a Disinfectant Against the Staphylococcus Pyogenes Aureus," published in the *Johns Hopkins Hospital Bulletin*, Dr. A. C. Abbott brings forward some strong arguments against the efficacy of this agent as an antiseptic. To the employment, he says, of sublimate solutions upon wound-surfaces it is plain that there exist at least two serious objections. First, the albumin of the tissues and fluids of the body tends to diminish the strength of, or indeed renders entirely inert, the solution employed; and second, the integrity of the tissues is materially injured by the application of solutions of this salt.

The first objection cannot be met with certainty, for the surgeon possesses no means by which he can determine the amount of albuminous material with which his solutions are to come in contact, and in any case this large amount of albuminous material is an almost insuperable obstacle to complete disinfection with sublimate. He is, therefore, never in a position to say, *a priori*, that his efforts at disinfection of the wound are or are not successful.

The second objection is equally serious. During the past two years we have had sufficient evidence to lead us to believe that the normal tissues and fluids of the body possess the power of rendering inert many kinds of organisms which may have gained access to them. This function is therefore diminished, or, indeed, may be quite destroyed, by any agent which brings about alterations in the constitution of these tissues. We know that just such changes as those to which we refer are known to follow the application of sublimate solutions. It is plain, then, if we bring about in these tissues a condition of superficial necrosis, the condition following upon the application of sublimate, they are much less able to resist the inroads of infectious organisms than they would have been had they been left in their natural condition.

As a disinfectant, in the strict sense of the word, there are perhaps few substances which possess the property in a higher degree than does corrosive sublimate, but at the same time there is nothing which is employed for this purpose that requires greater care in its manipulation in order to obtain its best results than does this salt. As we have seen, its action is influenced by a number of conditions which in practical application it is difficult, if not quite impossible, to control.

For these reasons we seem hardly justified in continuing to give to it the first place in the list of substances which may be employed practically for the purpose of rendering harmless materials containing the germs of infectious maladies.

THE VALUE OF NOTE-TAKING.

THERE is a wide difference of opinion among practitioners as to the value of note-taking, many doubting whether the habit of keeping careful records of every case met with in practice really pays in the long run, and whether the time so spent could not have been more profitably employed in recreation or in study. Nothing has a more dreary, stale, and "back-number" look than a pile of filled-up records occupying needed space on the bookshelves, and serving apparently no purpose but to accumulate dust. As time goes by the utter worthlessness of these manuscript volumes becomes seemingly more and more evident. Medicine is ever advancing, new methods of diagnosis and new modes of treatment are constantly presenting themselves; and these despised records become even more valueless in our eyes as they bring out more and more clearly the evidence of past ignorance, and show us our former selves in the guise of blind gropers in the dark, so blind and in such black darkness that we did not even suspect it, but believed we were walking securely in the bright light of the noonday of accurate knowledge.

But let us look at them a little more closely. Can they teach us nothing? There is one lesson right here. We smile at the little knowledge of those days, and congratulate ourselves that at last the day has dawned and that we are here to see the bright sun rise. But the morning that looks so bright to us now, how will it look in the noonlight of the future? Will not those that come after smile at us as we smile at our former selves as portrayed in these old note-books? We may be on the right path now, but we have not reached the end, and we may as well practise a little humility, and not be too confidently assertive of the absolute correctness of our present position, for we may, by so doing, be only giving still greater occasion for mirth to our irreverent successors. And further, we can profitably turn to these "back numbers" for other reasons. We are going along so rapidly and continually acquiring information concerning matters of such seemingly great import, that we are in danger of forgetting many things of perhaps smaller moment, yet most necessary to us in our daily work. Indeed, we have already forgotten much that would have been to our profit and the good of our patients to remember, and if we would refresh our memories we need but to return to our notes and see how many little points there are recorded there which we would do well to revive.

If our readers doubt this, they have but to read a most interesting little volume, lately published,[1] in which Sir James Paget recounts the results of an excursion which he recently made through the dusty pages of his old case-books. There is nothing dusty about the book, it reads

[1] Studies of Old Case-Books, by Sir James Paget, Bart. London: Longmans, Green & Co. 1891.

like a record of new discoveries, as indeed it is. It is a presentation by a master hand of a great deal of rare information on practical subjects, and even if, perchance, the reader find nothing that he did not once know, he will, nevertheless, have recalled to him a good deal that he had buried so deep in his memory-case as to hide it away beyond any chance of spontaneous recall We cannot refer now to any of the most interesting subjects suggested to the author by this re-reading of his old manuscript records, but we shall notice later some of the points presented, not only because they are interesting in themselves, but also to show what wealth there really is in old note books, and how much we can learn by carefully studying them in the light of our present knowledge.

THERAPEUTIC HINTS.

Medical men are sometimes so fascinated with the pursuit of knowledge for its own sake that they lose sight of the one great end and aim of medical study, which is, or should be, the alleviation of suffering and the prolongation of life, as affected by the prevention and cure of disease. The two branches in which these objects are more particularly studied, and to which all other branches are but auxiliary, are hygiene and therapeutics. Hygiene has become in these days a science apart, and one which interests and attracts to itself many earnest students among the laity as well as in the ranks of the medical profession. But therapeutics, the healing art, is one studied and scientifically and safely practised only by the trained physician.

It is true therapeutic scepticism is just now prevalent, and it is very much the fashion to decry drugs, to regard most diseases as incurable, or rather self-curable, and to put faith chiefly in diet and careful nursing, leaving to the vis medicatrix naturæ, the phagocytes, or something else, the cure of the disease. A truly scientific scepticism is commendable, but there is danger of going too far, and incredulity carried to the extreme may become credulity in another form. We may confess that there are many diseases that we cannot yet cure, but we dare not say that they will always be beyond our skill to overcome, veritable opprobria medicorum. It is very possible that the time will come when the therapeutist, basing his researches upon the findings of the bacteriologist and the pathologist, will be able to cure typhoid fever or pneumonia as readily and as certainly as he now relieves many of the aches and pains and other minor ills that afflict humanity. But he will never accomplish this by folding his hands with the quiet resignation of despair. He must have hope and confidence in the ultimate success of his own or others' efforts, and must cure himself of the habit of looking upon disease as an indomitable foe.

Physiology, pathology, bacteriology, and all the other collateral medical sciences, are subsidiary to therapeutics, and a rational method of cure must rest upon the knowledge furnished by them. But while waiting for this knowledge the therapeutist cannot be idle; disease is ever present and he must fight it with the weapons that he has until other and better ones are put into his hands. For this reason empiricism must enter largely into therapeutics, and every physician must be an empiricist to a great extent if he will relieve his patients. Often, indeed, empiricism precedes a scientific knowledge of drug action. It was known that aconite would lower temperature, and the knowledge was acted upon to the relief of suffering long before any explanation of this action was had. We cannot, therefore, despise empiricism nor obstinately refuse to employ a remedy simply because we are as yet unable to give a rational explanation of its curative effect.

In this department of minor therapeutics, if we may so call it, there is much that everyone may learn, and much, too, that most physicians may teach their brethren. Every man has his favorite remedies and his favorite methods of administering them, and he may often do a real service to his fellows in sharing with them the results of his own experience. We have for this purpose opened a new department in the columns of the Record, and we invite contributions to it from all our readers. They must be short, in the nature of hints rather than treatises, and practical. Prescriptions, new applications of old remedies, effective methods of administering drugs, practical hints and wrinkles of all sorts that will tend to the comfort and relief of the suffering and the cure of their ills, these are what we want for this column, and what we hope our readers will contribute for the good of all. We shall also present here whatever we may find of this nature floating about in medical literature in this country or abroad. Due credit will be given wherever the source of the information can be traced, and the names of all those who favor us with their contributions will, of course, be given; in fact, we desire that such should be the case, in order that no mistakes in dosage and methods of administration may be made and that due responsibility should be shared regarding the same. The practical usefulness of this department will rest largely with the readers of the Medical Record themselves, and relying confidently upon their co-operation we present the first instalment of "therapeutic hints" in this issue.

THE THERAPEUTICS AND PHYSIOLOGY OF BLEEDING.

According to Dr. Pye-Smith venesection is indicated in— 1. Cyanosis with distention of the right side of the heart, whether from pulmonary or other obstruction to the circulation. 2. Intense pain of aortic aneurism. 3. Uræmic and prolonged epileptic convulsions. It is contra-indicated in fevers, inflammatory disorders, acute pneumonia, hemorrhage, and apoplexy.

The physiology of venesection has recently been studied again by Professor I. M. Dogiel (*Vratch*, in *London Medical Recorder*). His experiments were conducted mainly upon dogs and he comes to the following conclusions: 1. Dogs can survive, without any permanent injury to their health, after having lost from one-seventh to one-half of the animal's total mass of blood at a time. The extraction of two-thirds of the total, however, is invariably followed by death. 2. Blood-letting manifests a sharply pronounced influence on the frequency of the cardiac beats in the case of a moderately large depletion (from one-seventh to one-third of the total quantity of blood), the cardiac action becomes accelerated, while after larger losses it either quickens or becomes slower. 3. Blood-lettings also produce a marked effect on the rhythm and energy of the cardiac contractions (as details). 4. Mild bleedings

(made by means of ten or fifteen leeches) either do not alter the arterial tension, or slightly raise it. More or less considerable arterial bleedings either do not affect the blood-pressure, or are followed by a fleeting initial fall with a subsequent rise, while venesections commonly lower the tension. 5. After moderate depletions "the pulse-wave acquires a periodical character." 6. In the beginning of a bleeding the bodily temperature slightly rises, then sinks about 20° F., and afterward again gradually rises. 7. On repeated depletions (made every three or four weeks) the bodily weight at first increases—and that sometimes "very considerably"—but later on begins to sink. 8. The same holds true with regard to the numerical strength of red blood-corpuscles. 9. On the post-mortem examination of animals dying from bleedings the most prominent feature proves to be a fatty degeneration of the heart and other striated muscles, as well as various viscera. In the course of a discussion, Professor A. B. Vogt and Dr. S. M. Shtcherbakoff have stated that, according to their experiments, bleedings do increase not only the number of red blood-corpuscles, but also the proportion of hæmoglobin.

THE MEDICAL PROFESSION IN RUSSIA.

Some interesting statistics concerning medical practitioners in Russia have recently been collected by Dr. Grebenschikoff, and published in the official bulletin of the Medical Department in St. Petersburg. From an abstract of the same in *Le Progrès Médical* we gather the following facts concerning our confrères in that country:

The total number of physicians in Russia on July 1, 1890, was 12,521, of which 409 were women. Surgeons of the army and navy made up twenty-one per cent. of this number. Of physicians in civil life about two per cent. are engaged in teaching, ten per cent. are attached to hospitals and other institutions, two and a half per cent. have given up the practice of their profession, fourteen per cent. are attached to the Zemstvos, twenty-five per cent. are practising in the cities, and others are attached to schools, factories, sanitary works, etc. On an average for the entire empire there are 8.4 physicians to every 100,000 inhabitants; but as one-third of all the practitioners are resident in nine of the principal cities, the proportion for the rest of the country is much lower than this; in Siberia, for example, there being only 3.8 doctors to every 100,000 inhabitants. The country districts best supplied with doctors are those on the western frontier, practitioners seeming to prefer, as a rule, those parts in which the Zemstvo has no jurisdiction. The three cities best supplied with physicians are, as would naturally be supposed, St. Petersburg, Moscow, and Odessa. About one-quarter of all the female practitioners are to be found in the three cities just mentioned, most of the remainder being attached to the Zemstvos. Of the men, about twenty-two per cent. are specialists, one-half of these being located in the University towns. As regards nationality, it was found that only a little more than one-half were Russians, one-seventh being Poles, one-eighth Hebrews, and one-thirteenth Germans, the latter being for the most part settled in the Baltic Provinces, where they constitute more than seventy-five per cent. of the total number of practitioners. The average age for men completing their studies is 25.9 years, that for women being 26.8. The oldest man in practice is aged eighty-eight, and the youngest twenty-three; the oldest woman is fifty-seven years of age.

More than two thirds of the physicians are married, the largest proportion of married men being found among army surgeons, and the smallest among those in civil life. Of the married, sixty-eight per cent. had children, the great majority of them, however, having but one child, although there were twelve happy fathers out of the whole number who had thirteen or more children. There does not appear to be much wealth among our Russian brethren, since but 615 men and 31 women are recorded as possessing real estate or other property. The salary of physicians attached to the public service varies from 200 to 7,000 roubles per annum, the more common figures running between 900 and 1,500 roubles, only two per cent. of those in this service getting more than 3,000 roubles. The average income of a physician practising in St. Petersburg is 2,200 roubles; in Warsaw, 1,500; in Moscow, 1,700; and in Odessa, 3,600. (A rouble is worth about eighty cents.)

Finally, the average age of the Russian physician at the time of death is fifty-one years. Among the causes of death are contagious diseases, including phthisis, 42.3 per cent.; diseases of the nervous system, 14.6 per cent.; of the heart, 6.5 per cent.; of the respiratory organs, nine per cent.; of the digestive organs, 7.3 per cent.; cancer, 5.7 per cent.; old age, four per cent.; and suicide, 3.2 per cent.

News of the Week.

The United States Medical Practitioners' Protective Alliance held its first annual meeting at Baltimore, June 11th and 12th. The Society was incorporated under the laws of Maryland. Officers for the ensuing year were elected and such other business transacted as was necessary to establish the Alliance on a basis of permanence. Addresses were delivered by the officers, and several papers on Alliance work in general were read and discussed.

The American Association of Obstetricians and Gynecologists will hold its fourth annual meeting, at the New York Academy of Medicine, 17 West Forty third Street, Thursday, Friday, and Saturday, September 17, 18, and 19, 1891, under the presidency of Dr. Adam H. Wright, of Toronto. All physicians interested in the discussion of subjects pertaining to abdominal surgery, obstetrics, and gynecology are invited to attend without further formal notice. By order of the Executive Council, William Warren Potter, M.D., *Secretary*.

American Neurological Association.—The preliminary programme of papers to be read at the Seventh Annual Meeting, to be held at Washington, D. C., September 22, 23, and 24, 1891, is as follows: "A Case of Polio-Myelitis Anterior—Death on the Twelfth Day, with the Account of the Microscopic Examination made by Dr. C. W. Burr," by Dr. Wharton Sinkler, of Philadelphia; "A Contribution to the Therapeutics of Polioymelitis," by Dr. V. P. Gibney, of New York; "Poliomyelitis Acuta Adultorum," by Dr. William C. Krauss, of Buffalo;

"Double Athetosis," by Dr. William Osler, of Philadelphia; 1, "Report, with Specimens, of a Case of Multiple Neuritis;" 2, "Case, with Specimens, of Lead-Poisoning, followed by Locomotor Ataxia, terminating Fatally by Uræmia;" 3, "Exhibition of a Porencephalic Brain;" 4, "Report of Two Cases of Rare Myoclonic Disorder," by Dr. James Hendrie Lloyd, of Philadelphia; 1, "A Case of Thomsen's Disease;" 2, "Removal of Neuroma, followed by Disappearance of Local Anæsthesia of Fourteen Years' Standing," by Dr. G. L. Walton, of Boston; "A Case of Trephining and Excision of the Cortex for Jacksonian Epilepsy," by Dr. W. W. Keen and Dr. Charles K. Mills, of Philadelphia; "The Diagnosis of Certain Forms of Intracranial Syphilis," by Dr. Landon Carter Gray, of New York; "Recent Fissural Diagrams," by Dr. Burt G. Wilder, of Ithaca; "Syphilis of the Spinal Cord," by Dr. Philip Zenner, of Cincinnati; "Lead Poisoning with Special Reference to the Spinal Cord and to Peripheral Nerve Lesions," by Dr. E. D. Fisher, of New York; "Triple Personality," by Dr. Irving C. Rosse, of Washington, D. C.; "A Case of Glosso-Labio-Laryngeal Paralysis, with the Presentation of Specimens," by Dr. Graeme M. Hammond, of New York; "The Virile Reflex in Relation to Clinical and Forensic Neurology," by Dr. C. C. Hughes, of St. Louis; 1, "Facial Hemi-hypertrophy;" 2, "Five Recent Cases of Brain Surgery," by Dr. William A. Hammond, of Washington, D. C.; "A Case of Tumor of the Cerebellum, in which Trephining was Done for the Relief of Pressure," by Dr. Philip Coombs Knapp, of Boston; "Lithæmia Considered in its Relation to Nervous Phenomena," by Dr. C. Eugene Riggs, of St. Paul.

The Kentucky State Board of Health has passed a resolution to place upon the list of medical colleges whose diplomas are to be certified and endorsed for registration under the laws of the State, only such colleges as shall, after the session of 1891–2, exact of matriculates and graduates a minimum of requirements not less than those required by the American Medical College Association.

Professor Stephen Smith, M.D., LL.D.—At the recent commencement of the University of Rochester the honorary degree of Doctor of Laws was conferred upon Dr. Stephen Smith, of this city.

The American Dermatological Association.—The following is the Preliminary Programme of the Washington Meeting of the American Dermatological Association, September 22 to 25, 1891: "President's Address," by Dr. F. B. Greenough, of Boston; "Discussion on Tuberculosis of the Skin," opened by Drs. White and Bowen, of Boston, and Fox, of New York; "A Therapeutic Note on Alopecia Areata," by Dr. L. D. Bulkley, of New York; "The Treatment of Alopecia Areata," by Dr. P. A. Morrow, of New York; "Remarks on Carbuncle, with Report of a Peculiar Case," by Dr. H. G. Klotz, of New York; "Dermatitis Hæmostatica," by Dr. H. G. Klotz, of New York; "Note on Erythema et Nævus Nuchæ," by Dr. C. W. Allen, of New York; "A Case of Lichen Ruber," by Dr. J. Grindon, of St. Louis; "A Case of Lichen Scrofulosorum," by Dr. J. Grindon, of St. Louis; "A Case of Lupus Erythematosus, with Fatal Complications," by Dr. W. A. Hardaway, of St. Louis; "Lymphangioma Circumscriptum, with Report of a Case," by Dr. M. B. Hartzell, of Philadelphia; "Notes of a Case of Acute Dermatitis Exfoliativa," by Dr. J. E. Graham, of Toronto, Canada; "Morphia Atrophica of Wilson," by Dr. R. W. Taylor, of New York; "A Study of Mycosis Fungoides, with Report of a Case," by Drs. H. W. Stelwagon and H. Leffingwell Hatch, of Philadelphia; "Diseases of the Skin Associated with Derangements of the Nervous System," by Dr. W. T. Corlett, of Cleveland; "Prairie Itch," by Dr. L. N. Denslow, of St. Paul; "The Treatment of Pruritus," by Dr. E. B. Bronson, of New York; "Note Relative to Pemphigus Vegetans," by Dr. J. N. Hyde, of Chicago; "The Personal Equation in Dermatology," by Dr. L. D. Bulkley, of New York; "An Unusual Case of Sarcoma Involving the Skin of the Arm — Amputation—Recovery," by Dr. F. J. Shepherd, of Montreal, Canada; "Multiple Sarcomata: History of a Case Showing Modification, and Amelioration of Symptoms with Large Doses of Arsenic," by Dr. S. Sherwell, of Brooklyn; "Thirteen Cases of Tuberculosis of the Skin with Their Treatment," by Dr. J. S. Howe, of Boston; "Treatment of Chronic Ringworm in an Institution for Boys," by Dr. L. A. Duhring, of Philadelphia; "Report of a Case of Universal Erythema Multiforme," by Dr. L. A. Duhring, of Philadelphia; "Notes of a Visit to the Leper Hospital of San Remo," Italy, by Dr. L. A. Duhring, of Philadelphia.—GEORGE THOMAS JACKSON, M.D., *Secretary*.

Trouble in the College of Physicians of Philadelphia.—A despatch announces that the resignations of the Board of Censors of the College of Physicians has been placed in the hands of the Secretary, Dr. Charles W. Dulles. The board consists of Drs. Goodell, Stillé, Hunt, and Da Costa. This action was taken because the college, by a vote of 45 to 40, postponed consideration of the board's recommendation that Dr. Joseph Price, a prominent member of the college, be censured for using slanderous language toward one of the Fellows of the college. It is understood that the final retirement of the board will depend largely upon the action that may be taken by the college at its September meeting. If the college should reconsider its postponement of the question and sustain the Board of Censors, the members may be induced to reconsider their resignations. They are loth to discuss their action, owing to the fact that they feel keenly the disregard by the college of their recommendations. A personal friend of the members of the board, who has discussed the matter with them, said to-night: "The College of Physicians was instituted in January, 1787, and after an existence of one hundred and four years this is the first time that the Board of Censors' recommendations have not been approved."

Hysteria in the Male.—In the article with this title, on page 675, vol. xxxix., the second word should be rarity instead of variety.

Gift to a Medical College.—The Medical Department of Tulane University has been made the recipient of a donation from Mrs. Richardson, wife of the Dean of the College, Dr. T. G. Richardson, of $100,000. The entire donation is intended to be used in erecting a new college building.

How Hot Springs was Not Selected as the Next Place of Meeting of the American Medical Association.—"Rather an amusing incident," writes a correspondent of the *Occidental Medical Times*, "occurred in connection with the Nominating Committee. Some thirty-six delegates, representing as many States, constituted the committee, and when the subject of the next place of meeting came up, there was considerable excitement. Dr. J. M. Keller, of Hot Springs, Ark., a man of considerable force, was extremely anxious that the Association meet next year in that city. Detroit had equally strong representatives, and had evidently done considerable trading to obtain the prize. California's cordial invitation was presented and ably seconded by Dr. Jenkins, of Iowa, President of the State Society. Omaha also wished to have the next meeting. After a half dozen ballots, in which Detroit and Hot Springs led, Hot Springs was selected. Dr. Keller was happy and immediately sent for refreshments at $5 a bottle, and dispatched telegrams of congratulation to his townsmen in Arkansas. The Nominating Committee had completed its work, was refreshed at Dr. Keller's expense, and the report presented to the Association was accepted with a single exception. That exception was Hot Springs, and Detroit won the day."

The Mississippi Valley Medical Association will hold its seventeenth annual session at St. Louis, Wednesday Thursday, and Friday, October 14, 15, and 16, 1891. Reduced rates and an excellent programme will bring out a large attendance. The medical profession is respectfully invited. The officers are as follows: *President*, C. H. Hughes, M.D., St. Louis, Mo.; *Secretary*, E. S. McKee, M.D., Cincinnati, O.; *Chairman Committee of Arrangements*, I. N. Love, M.D., St. Louis, Mo.

Koch Believes in his Lymph.—In a debate in the Upper House of the Prussian Diet, on June 18th, the Minister of Public Works, Ecclesiastical and Medical Affairs, replying to questions concerning the efficacy of Professor Koch's tuberculin, maintained that it had scientific value, and that its therapeutic value would be greatly enhanced as soon as Professor Koch had obtained a pure cultivation of the principal substance. This result, the Professor had informed him, would be achieved in a few weeks, and the composition of the "lymph" would then be submitted to the examination of the scientific world.

Organization of the School of Medicine of the University of Texas.—At a meeting of the regents of this University, held in June, at Austin, steps were taken to put the medical branch into operation next October. It was determined to arrange for eight chairs, with salaries affixed ranging from $3,000 to $2,000 each. Dr. H. A. West, of Galveston, was elected to fill the chair of Practice of Medicine, and Dr. J. F. Y. Paine, of Galveston, the chair of Obstetrics and Gynecology. The board determined also to have a three years' graded course, a session of seven months, and require an entrance examination. The medical branch of the University is located at Galveston. The State has about completed a building for the School on the block adjoining the Sealy Hospital, the gift to the State of Mrs. John Sealy. An election to fill the vacant chairs will take place in Galveston the latter part of August next.

Miss Garrett's Contribution to Johns Hopkins.—The conditional contribution of Miss Mary Garrett to the Johns Hopkins Medical School, referred to in our last issue, was $100,000, instead of $10,000 as stated in the journal quoted. The total amount of subscriptions to date for the inauguration of the co-educational project is something over $147,000.

Nathan Bozeman, M.D., LL.D.—The University of Alabama, at its Commencement in June, 1891, conferred the degree of LL.D. upon Dr. Nathan Bozeman of this city.

Measles on a Steamship.—There were thirty-two children sick with measles on the steamship Washington, which arrived in this port from Gibraltar on June 23d, out of a total of 971 Italian steerage passengers.

Dr. Stevenson, who was the surgeon in charge of the Andersonville prison during the Civil War, has just died in Halifax, in which city he has made his home since the close of the war.

Dr. Andrew B. Hoffman, an old physician in Hunterdon County, died at Annandale, N. J., on June 30th, aged eighty-three. He had practised medicine for sixty years.

Dr. Lorenzo S. Fox, of Lowell, Mass., died on June 23d, aged fifty-one. He had been connected with the staff of the Lowell Hospital since its foundation in 1881. He was a prominent member of the Middlesex Normal Medical Society and President of it in 1876.

A New Reception Hospital.—The Board of Health has recommended the establishment of a new reception hospital at the foot of East 138th Street, the accommodations of the Millard Parker Hospital and the reception hospital at the foot of East Sixteenth Street being insufficient.

Congress of American Physicians and Surgeons.—The second triennial session of this Congress will be held in Washington from September 22 to 25, 1891. A number of distinguished physicians and surgeons from Europe and Spanish America have accepted the invitation to attend. The sessions of the Congress will be held in the main hall of the Grand Army Building, 1412 Pennsylvania Avenue, from three to six P.M. daily. On Wednesday evening, September 23d, the President's address will be delivered in the lecture-hall of the National Museum at eight o'clock, and will be followed by a reception. The Army Medical Museum will be open the same evening. On Thursday evening the members of the American Surgical Association and of the Association of American Physicians will conjointly entertain their foreign guests at dinner at the Arlington Hotel. The American Gynecological Society and the American Pediatric Society will also give dinners on the same evening. On account of the large number of societies that will be in session at the same time, it will be advisable for those intending to be present to make an early arrangement for hotel accommodations. Arrangements are in progress to secure a reduction in railway fares, all inquiries in relation to which should be addressed to Dr. S. S. Adams, 1632 K Street. The Committee of Arrangements will take pleasure in answering any inquiry relating to the local arrangements of the Congress. The chairman of this committee is Dr. Samuel C. Busey, No. 1545 I Street, N. W., Washington, D. C.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Twenty-fifth Annual Meeting, held at the West End Hotel, Long Branch, June 23 and 24, 1891.

DR. JAMES S. GREEN, OF ELIZABETH, PRESIDENT, IN THE CHAIR.

Committees on Credentials and Arrangements.—DR. WILLIAM PIERSON, of Orange, read the report of the Committee on Credentials, which was accepted. Dr. H. Mitchell read the report of the Committee on Arrangements.

Medical History of the State for the Past Year.—This history was based on reports sent the Standing Committee from members of the profession in the several counties. La grippe was reported as having prevailed with various degrees of intensity in different counties. Common complications were affections of the respiratory tract, pneumonia in particular causing many deaths. Prostration was marked. Intermittent fever, remittent fever, and typhoid fever, also cholera infantum and diphtheria, had been far less prevalent in the State during the year than usual; while pneumonia and catarrhal affections in general, rheumatism, and rubeola had increased. Zymotic diseases generally had been of mild type. The reports of the Corresponding Secretary, Dr. William Elmer, jr., and of the Committee on Honorary Membership, Dr. H. R. Baldwin, Chairman, were read and accepted.

Permanent Delegates.—The report of the Committee on Permanent Membership, read by the Chairman, Dr. H. Mitchell, recommended the creation of permanent delegates, to be elected by the several district societies, the object being to increase the attendance and interest in the State Society. The report, with its recommendations, was adopted.

A View of Modern Surgery from the Stand-point of a General Practitioner.— DR. JAMES S. GREEN chose this subject for his presidential address. The era of modern surgery, he said, commenced with the discovery and practical use of anæsthetics. After mentioning the introduction of ether and chloroform in general anæsthesia, he said that cocaine had not been fully appreciated by the profession at large.

Care of Wounds.—The inference to be drawn from the various and conflicting methods formerly advised for the dressing of wounds was that they were all empirical, the result of ignorance of the fundamental principle which governed the surgeon in this more enlightened day. Formerly surgeons sought to produce suppuration and prevent primary union; modern surgeons aimed to prevent suppuration and to secure union by primary intention. He said that Tait's unfair and irrational criticisms upon antiseptic surgery had been entirely destroyed by Dr. J. William White.

An important advance in surgery followed the introduction of methods of preventing hemorrhage during operations.

Without attempting to cover the entire field in which modern surgery had made marked advance, attention was called to the success which now attended operations in abdominal affections, particularly appendicitis, which until lately had been left largely to the care of the general practitioner. Early laparotomy in recurring appendicitis was not only justifiable but was absolutely demanded.

Supra-pubic cystotomy, the treatment of phlegmon, and tenotomy also received short consideration. Burns should be treated more in accord with the teachings of modern surgery than was customary. In the hospital with which he was connected they cleansed the wound with a solution of bichloride of mercury, shaved and cleansed the adjacent surface, scraped away the dead tissue with the Volkmann spoon, and sought to avoid sepsis. The success of cerebral surgery was becoming more and more positive.

Before closing his address the President cautioned the young practitioner against choosing a specialty before a few years' general practice, in order that he might learn to which specialty he was best adapted. The moral obligations of the surgeon demanded that he look solely to his patient's interests. He feared, however, that some allowed themselves at times to give too much attention to completing a list of a hundred cases, successful or otherwise.

Intubation of the Larynx, with a Report of Eighteen Cases.—DR. WALTER B. JOHNSON, of Paterson, read the paper. He thought the operation had a greater future than tracheotomy could possibly have, although it was not intended to supersede this in certain directions. Some of the advantages of intubation over tracheotomy were enumerated as follows: 1, No anæsthetic was required; 2, the operation was easy; 3, there was little or no shock; 4, the general practitioner could do the operation without trained assistance; 5, the patient and parents more readily consented to an operation which was not accompanied by cutting or bleeding; 6, the percentage of recoveries was greater, especially before the third year; 7, no wound from which absorption might take place; 8, applicable in mild croup where tracheotomy would be too severe a remedy; 9, patient and parents were greatly pleased by the immediate relief of the dyspnœa; 10, the tube required comparatively little attention; 11, ability to speak while wearing the tube; 12, the contact of the tube caused some disintegration of the false membrane and hastened its disappearance—this pressure had also a decided tendency to diminish œdema; 13, the tube allowed mucus and detritus to be expectorated; 14, preservation of the explosive quality of the cough, rendering the tube less likely to fill with membrane; 15, the inspired air was more moist and warmer; 16, deep ulceration was not likely to occur.

The paper treated of the construction of the tubes, and the various phases of the subject of intubation, in an extended manner. The eighteen cases in which he performed intubation occurred during the seven months commencing with July, 1890, the severer part of the epidemic at Paterson. This accounted for the fact that only three of the eighteen recovered. In all there was very gratifying relief from dyspnœa.

Reduction of the Assessment.—DR. KIPP's report of the condition of the treasury showed such plethora that it was resolved to reduce the assessment for the present year to one dollar.

Tuberculosis; the Potential Factors in its Spread.—DR. EDGAR HOLDEN, of Newark, opened the discussion upon the subject presented at the last annual meeting, "Tuberculosis; the Potential Factors in its Spread, whether Hereditary Capacity, Inherited Bacillus, or Transmission from Inferior Animals?"

The etiological relation of the bacillus tuberculosis of Koch to the disease under discussion had been generally accepted except by a few authors. But further important questions related to the manner of introduction of the bacillus into the system, and to the vulnerability of the patient. There were two types of vulnerability, the one the result of inheritance, the other acquired. With the former, careful living and healthful surroundings would do much to prevent the implantation and development of tuberculosis. In the latter, where there was no inherited vulnerability or tendency to the disease, the attack upon the citadel of life was made because of lowered vitality and exposure to overwhelming numbers of the foe.

Modes of Entrance of the Bacillus.—Taking up the latter subject, the mode of entrance of the bacillus tuberculosis into the system, it had been shown to be at least possible by the following methods: By inhalation, by in-

oculation, by ingestion, and by inheritance. The most important of these was the first-named, inhalation of the bacillus with dried particles floating in the air, and the author cited some very interesting, and what he regarded as conclusive, evidence of propagation of the disease by this means. It was true, however, that healthy persons might be exposed in consumptive wards and not contract the disease unless something arose to reduce their vitality. Regarding the second method, he could only refer to the possibility of tuberculosis developing from inoculation with the bacillus, as through wounds made at autopsies or present on butchers' hands. It had been said that tuberculosis and small-pox never coexisted, but Dr. Holden felt sure that he had seen both diseases present in the same patient. There was no proof, however, that tuberculosis had developed from inoculation with vaccine matter.

Propagation by Ingestion.—The evidence regarding the propagation of tuberculosis by the ingestion of meat and milk was as contradictory as it was voluminous. Shirley and Gibbs claimed that the tubercle bacillus in animals was not the same as that in man. There was satisfactory evidence of the danger of eating meat of tuberculous animals, however limited might be the disease. The author thought it was not necessary that the udder itself should be diseased to make the milk of a tuberculous cow dangerous. State Boards of Health were waking up to the need of securing legislative action regarding tuberculous meat and milk. Four to twelve out of every hundred cows were tuberculous.

Influence of Heredity.—What might be called practical inheritance and actual or direct inheritance might be vitally different, but the testimony in favor of the former at least could not be easily brushed aside. Whether there was or was not direct transmission of the bacillus, he thought we could not but admit the inheritance of something, say a vulnerability, similar perhaps to the inheritance of a susceptibility to gout and some other affections. There was, too, some evidence noted by German observers in proof of the tubercle bacillus occurring in some instances in the fœtus.

But that a vulnerability was hereditary in consumptive families, the author did not doubt. He had published some facts going to show this in Wood's "Handbook of the Medical Sciences," comparing the longevity of persons applying for life insurance among whose near relatives there was no history of phthisis with that of persons who gave such a history. Of the former it had not been difficult to get a hundred above seventy five years of age for comparison, while among the latter he was compelled to choose from among persons below sixty. Yet the number of children to the family in the two classes averaged about the same—over six.

Dr. J. W. Stickler, of Orange, analyzed a series of cases of tuberculosis, over two hundred in number, reported by the late Professor Austin Flint, and some others, going to show that there was a hereditary tendency or vulnerability to the disease which had not escaped general observation although no adequate explanation for it had been offered. Regarding the second question, the influence of the bacillus, it was at one time claimed by the adherents of the parasitic origin of the disease that it was impossible for the mother to transmit it directly to the child, but more recently there had been a growing belief that this was possible. He quoted observations bearing on this point. If there was danger of direct transmission of the disease to the fœtus, he thought it would be limited to cases of tuberculosis of the testes, of the ovaries, of the placenta, or cases of general infection. As to the danger of propagation of the disease from animals, he thought it was greatest from milk. But, in agreement with the author of the paper, he thought the most potential of all factors was association with those affected with tuberculosis, and next came hereditary vulnerability.

The discussion was continued by Drs. Benjamin and Baldwin.

New Jersey Cows.—Dr. Henry L. Coit, of Newark, read the report of the committee "to investigate the subject of the influence of diet and care of cows upon the constitution of their milk, and the action of this milk upon the human subject when it proves injurious. Further, to determine what current practices in their feeding and care are prejudicial to this product."

Dr. Coit read a paper bearing on this subject at the last annual meeting, and was authorized to form a committee to investigate it, and report to the Society. He had not yet finished the work, which he had found a great one. The committee was to be composed of two physicians in each county. Progress was reported, and by his request the committee was continued.

Medical Library at Trenton.—The report of the Committee on Medical Library to be located at Trenton, was read by Dr. Elmer. The library is to be located at that place.

The Treatment of Appendicitis.—Dr. John G. Ryerson, Third Vice-president, read a paper on this subject which bore the title, "Some Recent Views on Peritonitis." Limiting his remarks to appendicitis, he quoted Ferguson, who had shown in 200 autopsies that in 123 the mesentery of the appendix was so placed that, had perforation taken place, it could have opened directly into the peritoneal cavity. Until a few years ago it was thought best not to cut down over the abscess until the fifth day. Under the teaching of McBurney, Bull, and others, it had come to be regarded among surgeons as best to operate as early as the second or third day; that in doubtful cases exploratory laparotomy should be performed and the appendix removed; that a high degree of surgical skill was required; that the surgeon should be called in early by the attending physician, and he should afterward, if possible, make frequent visits in order to become familiar with the case by personal observation. Taking the figures of Fitz, Bull, Noyes, and others, on which the so-called advanced surgical views of to-day were based, the author stated that fifty per cent., or forty per cent. at least, of the mortality was due to a septic form of peritonitis, and in this form recovery rarely took place. But formerly the mortality in all cases, from all forms of treatment, was twenty-five per cent., and before the recent so-called advanced surgery in this department had come in, the mortality had been reduced to fifteen per cent. Now, if forty per cent. of these fifteen deaths out of one hundred cases were of the septic form, which under any mode of treatment would prove fatal, it left only five per cent. of all cases on which the advanced surgery was to establish its claims. At best this could not be in the aggregate very great, and was likely to be more than offset by the dangers of surgical interference in some cases which under medical treatment would have got well.

The author advocated the opium treatment, introduced by Alonzo Clark, in opposition to the more recent saline and surgical modes of treatment. Opium was indicated for paralyzing peristaltic action, thus permitting the seat of inflammation to become encapsulated, and for allaying pain.

Is Appendicitis Epidemic?—Certain facts pointed toward the epidemic character of appendicitis: 1, At times its widespread occurrence; 2, its history; 3, its more frequent occurrence in young persons; 4, the local lesion was in a mucous membrane, as it it was in other epidemic diseases. It was not impossible that a germ would in time be discovered as the cause.

New Jersey Surgeons and Abdominal Surgery.—Dr. Edward J. Ill read a paper, the full title of which was "An Attempt to Show what New Jersey Surgeons have Done in Abdominal Surgery." As far as he had been able to elicit information by correspondence, only a few operations, mostly for ovariotomy, had been performed between 1865 and 1870, and not many up to 1875. From the latter date the number of cases had progressively increased to the present. Most of the cases had

occurred since 1887. The paper was necessarily incomplete, as it related to the work of other surgeons, but contained a condensed history of the more interesting of over ninety cases of abdominal surgery occurring in the author's practice.

Delegates present from other States were: Dr. Crothers, of Connecticut; Dr. Swing, of Pennsylvania; and Drs. Furbeck and Willy Meyer, of New York.

Election of Officers.—*President*, Dr. E. J. Marsh, of Paterson; *First Vice-President*, Dr. George T. Welch, of Passaic; *Second Vice-President*, Dr. John G. Ryerson, of Boonton; *Third Vice-President*, Dr. Sproull; *Corresponding Secretary*, Dr. William Elmer, jr.; *Recording Secretary*, Dr. William Pierson, of Orange; *Treasurer*, Dr. Archibald Mercer. Place of next meeting, Atlantic City.

Therapeutic Hints.

Persistent Dandruff.—Dr. Stephen says the following is very useful in persistent dandruff:

℞ Resorcini, ʒ
Ol. olivarum,
Ætheris sulph.....āā ℥iij.
Spt. vini. rect..... ʒ vjss.

To be well shaken and applied to the scalp by a bristle brush about twice as large as the ordinary mucilage brush, by insinuating it with the locks of hair. The head to be well washed with soap and warm water twice a week.—*Weekly Medical Review.*

Alcohol in Gangrene.—Dr. Allingham reports, in the *Canada Lancet*, a case of gangrene of the finger which was steadily advancing into the hand in spite of active treatment. He finally succeeded in checking further progress by immersing the hand in a vessel of alcohol kept warm by means of a coil of rubber tubing in the bottom of the pitcher through which hot water was made to flow. After about sixty hours the alcohol bath was replaced by one of boracic acid solution kept warm by means of the coil of rubber tubing. This acted as a poultice, and in a short time the gangrenous portion separated, leaving enough living tissue next the bone to throw out granulations.

The Hypnotic Action of Hot Compresses.—In certain cases of insomnia Dr. Alldorfer has obtained excellent results by means of bandages soaked in hot water, applied around the abdomen and lumbar region and covered with rubber cloth in order to prevent evaporation, a flannel bandage being applied over all to retain the heat.

Brown-Séquard's Emulsion.—Dr. P. Victoroff read a paper at the Fourth Congress of Russian Physicians in Moscow recounting his experiments with Brown-Séquard's testicular fluid. He had experimented with it in a large number of different affections, among which were locomotor ataxia, chronic myelitis, neurasthenia, diabetes mellitus, enlarged prostate, cystitis, senile marasmus, and paralysis of the bladder. From the results of these experiments he came to the conclusion that the fluid is without doubt endowed with a stimulating effect upon the central nervous system, acting as powerfully on women as upon men. The best results were obtained in senile marasmus and in nervous affections occurring in the aged.—*Vratch*, No. 3, 1891.

The Treatment of Sprains.—Dr. N. W. Cady, of Logansport, Ind., writes: "A recent number of the MEDICAL RECORD promises fame to the man who gives an unfailing remedy for sprains. Here it is, in two words: A half-hour's douching with water at a temperature of 120° F., and the fixation of the joint by a splint on the flexor side of the joint, or upon the extensor side, if that be more convenient. For example, in a case of ankle sprain, after a half hour's steady douching with hot water at 120° F., I prepare an anterior splint of ten to sixteen layers of mosquito-bar which, is thoroughly filled by immersion in wet plaster of Paris. This is trimmed by spreading it on a board and cutting to shape with a knife. The length may be thirteen to sixteen inches, breadth four to six inches. Where the splint passes over the instep the edges on each side are folded over to make the splint narrower and thicker. A layer of cotton is then spread over the face of the splint and the splint is applied from the base of the toes to a point about half-way up the leg and carefully secured and moulded by a narrow roller bandage. While the plaster hardens hold the foot in whatever position is easiest to the patient. There is rarely any further complaint of pain if the splint fits neatly. This, with perfect rest, constitutes the whole treatment, which should continue at least a week or until all extravasation is absorbed. Fourteen years' experience and observation of results obtained by other methods satisfies me that it is the best and most rational treatment."

Poultices in Typhoid Fever.—The late Dr. William S. Thompson, of Warren, Md., enjoyed a great reputation among both his medical brethren and the laity on account of the almost uniformly successful issue of the typhoid fever cases submitted to his care. He gave few drugs, but relied chiefly upon the application of thin poultices covering the entire abdomen, which were continued throughout the course of the disease.

Earache.—The following is recommended for the relief of earache: Chloroform, 1 part; olive oil, 8 parts; put from twenty to thirty drops of this solution in the auditory canal, closing the ear with cotton. When the earache is due to a furuncle in the external auditory meatus, an application of a solution of 1 part of menthol in 20 parts of oil of sweet almonds often brings almost instantaneous relief.

A Substitute for Felt Splints.—When it is desired to use a felt splint, but the material cannot be readily obtained, an excellent substitute may be manufactured out of old cloth, in the following manner (*North American Practitioner*): Dissolve one pound of the best gum shellac in one and one-half pint of ninety five per cent. alcohol, adding one drachm of borax. This makes a solution of syrupy consistence which is applied with a brush to one side of a woollen cloth, the cloth being then thoroughly dried before the fire. When dry, a second coat is added. This makes a thin piece, which can be strengthened by placing another piece over it, with the prepared surfaces together, union between the two being obtained by pressing with a hot iron. Pieces of old cloth are better than new cloth, as they absorb more. The splints must be thoroughly dried, or they will not harden. When ready to apply, hold before the fire or in hot water, till soft, then mould to the part, and remove for a few moments until hardened; this can be expedited by immersing in cold water.

A Rare Antipyrine Rash.—Veiel describes a case of a patient in whom antipyrine always produced a peculiar skin rash. Soon after the dose was taken there was severe itching of the palms of the hands, the lips, the soles of the feet, and of the glans penis. The lips became œdematous, and large bullæ formed on them; two bullæ also formed on the hard palate and between the toes. On the soles and palms there were deep-red urticaria-like spots with sharp contours, which itched severely but did not form bullæ. The itch lasted three or four days; the bullæ on the lips dried in four or five days; those in the toes in about eight days; the spots on the palms, soles, and glans penis desquamated in large scales after about ten days, and had vanished in about three weeks.—*British and Colonial Druggist.*

Hot Solutions of Corrosive Sublimate.—It is asserted that the antiseptic effect of corrosive sublimate solutions is greatly increased by heating to a temperature of 100° F. and higher, a 1 to 10,000 solution at this temperature being equal in germicidal efficacy to a cold solution of 1 part to 500.

Boroglyceride for Aphthæ.—The *Medical Mirror* says that boroglyceride, locally applied, is infinitely superior to all other local applications for aphthæ or thrush, in the oral cavity of nursing infants.

Obstinate Hiccough has occasionally been arrested by pilocarpine.

Pruritus.—An ointment composed of five parts of menthol, 20 of balsam of Peru, and 200 of lanoline is very serviceable in relieving persistent itching. For pruritis ani the local application of a solution of corrosive sublimate, 1–2,000 is recommended. And in pruritus vulvæ much comfort is often afforded by a lotion composed of one ounce of hyposulphite of sodium, half an ounce of glycerine, and water enough to make twelve ounces.

Troublesome Cough.—A writer in *La Semaine Medicale* claims to have had very satisfactory results in cases of harassing cough accompanied with scanty expectoration by the daily administration of from one to three grammes (15 to 45 minims) of the tincture of naregania. This is a tincture of the bark of naregania-alata which has been used in dysentery and rheumatism.

Sciatica.—Among the many remedies proposed for the relief of this obstinate affection is phenacetin, given in doses of from six to eight grains every three or four hours.

Malaria.—Cases of chronic malarial poisoning, refractory to the action of arsenic or quinine, are reported to yield speedily to half-grain doses of picrate of ammonium. This drug may be given alone, or, preferably, in many cases, combined with either quinine or arsenic, or both.

Diuretine.—The accounts of the action of diuretine (theobromine-sodio-salicylate) have varied so much that it is not by any means certain whether this drug can be admitted on our list of reliable diuretics. All we can at present do is to form our own conclusions from the published results. Dr. Heissler has tried its effect on one healthy subject, four patients with heart disease, two with nephritis, and one with cirrhosis of the liver. His observations were made at three periods, viz., before, during, and after the use of the drug. The conclusions drawn from his results are as follows: 1. The drug certainly produces a rise of blood-pressure. 2. It is not only a diuretic, but has an action on the heart. 3. It gives remarkable results, especially in cases of "asystoly" without valvular incompetence. 4. When the heart muscle is diseased the diuretic effects are much less marked. 5. Diuresis is much more abundantly produced in acute than in chronic nephritis. Albumin is never increased as a consequence of the administration of diuretine. 6. No diuresis followed its use in the case of cirrhosis of the liver. 7. On the healthy man the drug has but little effect.—*Medical Recorder.*

Management of Whooping-Cough.—The following rules for the management of an ordinary case of pertussis are laid down in the *Revue Générale de Clinique et de Thérapeutique*, No. 3, 1891: *First period.*—Keep the child in the house, or, preferably, in bed, and give aconite and belladonna, adding opium if necessary. These remedies may be administered in combination, from ten to twenty minims (according to the age of the child) of a mixture containing equal parts of tincture of aconite, tincture of belladonna, and paregoric, being given in the course of the twenty-four hours. *Second period.*—Give drugs such as ipecacuanha. Treat also the dyspepsia, which is usually present. *Third period.*—Treat any tracheo-bronchial adenopathy by cod-liver oil, iodine, tonics, etc.

Scarlet Fever.—Acetate of ammonia in large doses (one-half to two drachms per diem according to the age of the child) has been employed with apparently good effect in cases of scarlet fever.

Headache.—Headache almost always yields to the simultaneous application of hot water to the feet and back of the neck.

Carbuncles.—Dr. A. E. Spohn, writing in the *Medical and Surgical Reporter*, states that he has had excellent results in the treatment of carbuncle by the external use of a ten per cent. solution of chloral hydrate in glycerine and water, applied constantly by means of absorbent cotton, combined with the internal administration of sulphide of calcium. He was led to use the chloral externally to relieve the pain, and was surprised to find that it also had a curative effect.

Herpes.—Leloir claims excellent results in the abortive treatment of herpes from the local use of one part of resorcin or menthol to fifty of alcohol. If there is much pain he uses gauze steeped in the following solution and covered with an impermeable dressing: Alcohol, one hundred parts; cocaine hydrochlorate, one part; extract of cannabis Indica, ten parts; mint essence, ten parts.—*Medical Standard.*

Alcohol in Erysipelas.—Dr. Stembarth has treated successfully a number of cases of erysipelas by the external application of alcohol. He paints the affected part and the healthy skin surrounding it every two hours with absolute alcohol, and claims to effect a cure in most cases within three or four days.

Cold in the Head.—For cold in the head, while in the acute congestive stage, there is no better remedy than gelseminum. One good large dose, say ten minims of the fluid extract, taken upon going to bed, will effectually dispose of this troublesome and uncomfortable affection. One dose is usually sufficient.—*Medical Compend.*

Quick Action of Drugs.—The *Medical World* says if you want a sure, speedy action from your drugs, as if you gave them hypodermically, administer them in hot water; one-half the dose will have the effect. The reason is obvious. If the dose be given in hot water it is quickly absorbed, and the force of the drug thrown upon the system at once. Few people realize how long the dose will remain in the stomach if that viscus be chilled. Beaumont found that a glass of ice water stopped digestion for one hour. This method of ministration is particularly suitable for the vegetable preparations, opiates, etc.

Tooth Wash.—

℞. Saccharin.....gr. xxx.
Sodii bicarbonatis.....gr. xv.
Ol. menth. pip.....♏. iij.
Alcohol.....ʒ vj.
M. Sig.: Put one teaspoonful in a small glass of water, and rinse the mouth thoroughly.

Boro-Citrate of Magnesia in Urinary Calculi.—Dr. N. Perez (*Albany Medical Annals*) reports the case of a boy, four years old, having a large calculus in his bladder. Before performing an operation he tried the application of the boro-citrate of magnesia, of which he gave fifteen grains dissolved in an ounce of syrup, one to three tablespoonfuls every day. After three days of this treatment a good deal of white sediment appeared among the mucus in the urine, which continued about one month, the other phenomena disappearing.

Chafing of Trusses.—De Garmo recommends highly the following, not only for use with trusses, but wherever a toilet powder is used for children:

℞. Amyli.....ad iv.
Cretæ gallicæ.....ʒ ij.
Alum. ust. } Acidi boracic. } .....āā ʒ ij.
Acidi carbolici } Ol. limonis }.....āā ʒ ss.
M. Sig.: Powder very fine.

Where an abrasion has once occurred and is slow to heal, on account of the constant wetting by the urine and the irritation of the truss, the author has found nothing better than the balsam of Peru.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

AN UNUSUAL CASE OF TYPHOID FEVER—A PROTRACTED CASE OF LEUCOCYTHÆMIA—THE CHANGES IN HEALTHY ARTERIES AND IN TENDON LIGATURES AFTER LIGATION—THE GENERAL MEDICAL COUNCIL—THE UNIVERSITY QUESTION IN LONDON.

London, May 30, 1891.

At last week's meeting of the Clinical Society Dr. Sidney Phillips read notes of a case of typhoid fever in an adult male in whom the femoral artery became occluded during convalescence, and acute maniacal attacks occurred. The attack was a mild one, but the heart's action was weak and irregular from the first. Sudden pyrexial attacks occurred during convalescence, and the left common femoral artery became blocked, with absence of pulsation in it and in the popliteal and tibial arteries. Pulsation gradually recurred in the limb, which completely recovered. The fourth, fifth, and sixth attacks of fever were accompanied by outbreaks of excitement—almost of acute mania—and in one the temperature rose to 106.1° F. The patient eventually got quite well. Dr. Phillips remarked that a rise of temperature in the affected limb after occlusion of the main artery was not usual, and even if the ordinary collateral circulation was sufficient to keep the temperature of the part up to the normal, it could not be credited with raising it above the normal. It seemed probable that the shock of the embolism led to a reflex paralysis of the spinal centre—producing the retention of urine which had occurred—and that the same shock in the same way led to paralysis of the vaso-motor constricting nerves of the arteries of the lower limb, allowing an unusual hyperæmia. Dr. Gaskell had shown that these nerves originated in the anterior cornua of the spinal cord and passed out in the anterior nerve-roots to the sciatic plexus. Anything, therefore, which would produce a paralyzing influence on the spinal centres for the bladder might also paralyze the centres of origin of the vaso-motor nerves to the arteries of the leg. The maniacal attacks were possibly embolic in origin, but were more probably only signs of functional nerve disturbance in an emotional individual.

At the same meeting of the Society Dr. Ord read notes of a case of leucocythæmia which had been under observation for nearly three years before it ended fatally. The patient was a schoolmaster, aged thirty-six, and the disease certainly dated from as far back as 1886. The accessory symptoms were few. The patient suffered severely from headache, and had occasional hemorrhages from the nose and gums, also retinal hemorrhages. There was a variable amount of albumin in the urine but no marked variations in temperature. The patient was treated by rest, feeding, and the administration of arsenic and hypophosphite of soda. The arsenic appeared to be especially beneficial. It had been given in the form of liquor arsenicalis in doses of from five to ten minims three times a day.

At the last meeting of the Medical and Chirurgical Society, Dr Sheridan Delépine and Mr. C. T. Dent read a paper in which they gave an account of the changes observed in healthy arteries and in tendon ligatures during the first four weeks after ligation. As the result of their observations they concluded: 1. That tight ligation of healthy arteries resulted in sound and permanent obstruction within two weeks. 2. That tight ligation with flat tendon ligature did not injure the fibrous coat of the artery, even though the ligature were applied with sufficient force to cause complete rupture of both internal coats. 3. That the obstruction of the vessel by young fibrous tissue, replacing the clot, was complete long before the flat tendon ligature showed any signs of being absorbed or of giving way. The authors advocated the use of tendon because this material was very uniform in structure and because the shape presented certain advantages. They thought tight ligation was advisable as being the method least likely to lead to injurious consequences to the ligatured vessel and most likely to bring about the effects which it was commonly desired to obtain by the operation.

Some discussion followed the reading of the paper. The President (Mr. Timothy Holmes) said he had devoted a good deal of thought to the subject and had come to the conclusion that it was safer and easier for the surgeon, as well as more prudent for the patient, to have the vessel tied with such an amount of force as to divide the internal coat. This incurred no extra danger, and one was sure of producing a permanent obliteration of the lumen of the vessel. In the history of many of the cases of arterial ligature which had been done badly, the cause was found to be due to a too early establishment of free circulation through the weakened vessel; the danger was a practical one, and was greater than the theoretical benefit from the avoidance of rupture of the internal coat.

Mr. Macnamara agreed that the tight ligature gave the greatest chance of recovery to the patient. Mr. Ballance said he hoped the profession would suspend their judgment on this question till the whole of the recent work of Dr. Edmunds and himself was before them.

Mr. Spencer Watson pointed out that the experiments which had been narrated had been performed on healthy arteries, but surgeons were often called on to deal with atheromatous vessels when perhaps a loose ligature would be safer.

Dr. Delépine and Mr. Dent then replied and defended the position they had taken.

The spring session of the Medical Council commenced a few days ago. So far no very important business has been transacted. Sir Richard Quain has been elected as President, and Mr. Bryant as Treasurer, of the Council. Dr. Haughton made an ineffectual attempt to again discuss the question of the extension of the medical curriculum and a good deal of time was spent in the consideration of some resolutions with regard to the instruction of students in practical midwifery, the result being to reaffirm—with a verbal alteration—a previous resolution of the Council.

The university question in London has entered upon a new phase. Within the last few days University and King's Colleges have received formal notice that they are to appear by counsel before the Privy Council at an early date in support of their petition for the grant of a charter to a body of persons to be a University in and for the London district.

SPREADING DISEASE BY THE CLINICAL THERMOMETER.

To the Editor of the Medical Record.

Sir: I notice an article in the Medical Record, May 16th, headed "Dentistry and Syphilis," which reminds me of the thoughtless and filthy manner I have seen the clinical thermometer used by physicians, and that by physicians of good standing and undoubted ability. I cannot call to your attention any particular case that would demonstrate, without doubt, my views; but my conviction is sufficient to prompt me to make the assertion that disease is often conveyed by the clinical thermometer.

I have seen the thermometer used when the amount of mucus accumulated on it was so great as to make it almost difficult to see the register. The majority of practitioners wipe the instrument off with a handkerchief, towel, or even the bedclothing, and carefully place it away in a case prepared with a small amount of absorbent cotton in the bottom to prevent breaking, and, unintentionally, to preserve the germs from time to time, to be conveyed to

the next unfortunate, who may be the first patient called upon.

I make it a rule to clean my thermometer every time it is used, whether I suspect any infectious disease or not, at the patient's residence. I use soap and water, and if no disinfectant is at hand, I use, on my arrival at my office, either boracic, carbolic, or corrosive sublimate solution, in order that I may use my thermometer with a clear conscience when it is again needed.

L. M. Powers, M.D.

Los Angeles, Cal.

New Instruments.

A UNIVERSAL DOUBLE-ACTING SNARE, WITH PRACTICAL OBSERVATIONS ON ITS APPLICATION.

By CHARLES A. BUCKLIN, A.M., M.D.,

new york.

It is difficult to give proper credit to whom it is due in presenting a snare which is a combination of the good principles of all other similar instruments. Without the tempered steel wire all snares are indifferent surgical appliances.

I am unable to discover with certainty who is entitled to priority in using tempered steel wire in this connection. The best information I can gain about this subject is the following:

There were four snares made, over thirty years ago, using the same tempered wire which we now have. The instruments were made at Celle, in Hanover, Germany. The first one was made for Medicinalrath Dr. Scheller; Dr. Schmidt, of the same place, owned the second, and Dr. Marquandt owned the third. I am unable to determine who owned the fourth. The snare was considered a great success, as being the best means of removing nasal polypi. There were many more made at that time. The instrument consisted of two cannulas, fastened at one end to a cross-piece, which was firmly grasped in the hand. The steel wire was attached to a ring, which hung free some inches in front of the cross-piece. The operator passed his second finger through the ring and drew the wire loop firmly home by a strong grasp of the hand. At this time, for growths of a more dense character, this wire was not considered strong enough; a much larger size was used, which could only be managed well when the temper was drawn. In this more powerful instrument the loop has been drawn by a screw motion, and also by a ratchet motion.

Much credit is due Dr. Jarvis for suggesting a wider field of application of the tempered wire, drawing both wires through the same cannula, drawing the tempered wire with the screw motion, and for the general introduction of the advantages of the above principles.

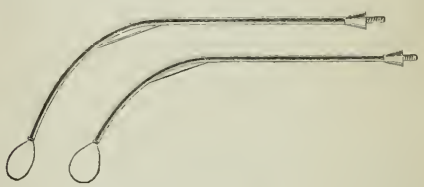
The modifications of drawing a steel-wire loop have become as numerous as the patterns of vaginal specula or nasal saws.

Sajous suggested a modification of the Jarvis snare having a solid stylet, to the end of which the wire was attached. This instrument had the advantage of using much less wire, and the loop, after being drawn, could promptly be returned to position for repeating the operation. The advantages on paper appear attractive. In practice the difficulties encountered make the instrument thoroughly impracticable. In the Sajous snare the friction of the ends of the wire, which are doubled over the stylet, offer a decided resistance to the rapid engaging of a growth by sliding the loop without the use of the screw. This will be found in practice a fatal objection.

The advantages of being able to engage a growth with one hand, while the other is left free to adjust the head, the light, or a speculum, has led to the construction of a large number of snares, in which, for the purpose of carrying the operator's hand out of the line of vision, the handle stands at an obtuse angle to the line of traction. The power in this class of instruments consists of a nut running on a thread, which encircles the handle. This necessitates an angular traction on the wire, or a decided off-set from the carriage on the handle. In either case the binding is severe, the instrument is not constructed on true mechanical principles, it is weak, and only answering for the very lightest class of work.

Dr. Wright started out with the fixed idea of creating a snare which did not draw by a screw motion. The result was a very satisfactory instrument. He appropriated Sajous's stylet, and overcame all the disadvantages of other instruments in the following manner: He applied a firm handle to the tube carrying the stylet. This carried the hand out of the line of vision. He drew the loop by a ratchet motion, which is worked by the thumb of the hand holding the instrument. This instrument is very powerful. The line of traction is straight, and I think it is more easily adjusted about a growth than any other form of snare. The objections urged against the instrument are that it is rapid cutting and dangerous in very vascular growths, and that it is too heavy to use where a very slow process of strangulation is required.

After carefully experimenting with all forms of snares, I have attempted to make use of the good features in all, and combine them in one instrument.



The instrument which I present to you may be made to meet any possible emergency in a manner which meets the approval of the most timid and conservative operator.

The stylet of Sajous is used, and as no attempt is made to adjust the wire excepting with the rapid-acting ratchet motion, the difficulties of resistance are entirely overcome. The screw action and the ratchet action are connected to the same stylet, enabling one at pleasure to use a very slow-cutting snare, or a most satisfactory rapid-cutting one. The handle and ratchet motion are detachable at pleasure, leaving one an instrument suitable for the slow strangulation of a very vascular growth. In adapting this instrument for the removal of adenoids through the pharynx, certain foreign bodies lodged in and about the larynx, as well as certain intra-laryngeal growths, I thoroughly experimented with flexible stylets, and rejected them as impracticable and dangerous. They are certain to bind and break sooner or later in making the transit of the curve.

With a properly constructed instrument a few minutes' instruction will enable anyone to arm these curved tips with wire quite as quickly as any other curved tip can be armed.

The question now arises, Where should the slow motion be used, and where should the rapid motion be used?

There are three factors to be considered in answering this question. The most important one is the personal ideas of the operator regarding hemorrhage. Some men are very timid, others fear nothing short of the carotids, a nævus, or a suspiciously vascular-appearing growth. The second factor is the real nature of the growth. The third factor is the age of the patient. Adults bleed much worse than children as a class.

The last two hundred cases of which I have any memoranda upon whom I have used a snare, in not more than twenty-five cases should I have made use of the screw motion attached to this instrument. Others may have used it in half of the cases. If out of two hundred cases

it was found desirable to use a rapid acting snare one hundred and seventy-five times, the advantages of having a rapidly acting snare can be readily appreciated. The annoying disadvantages of using a rapidly acting snare on a highly vascular growth, which are of exceptional occurrence, should not deprive us of the use of the rapidly acting snare in cases where no excessive degree of vascularity exists.

I have experimented with this instrument some thirty times on the removal of the tonsils. It has been my custom in timid patients, where both tonsils are enlarged and neither are bound down by adhesion, to take an instrument of this pattern in each hand, and carefully adjusting a loop about each tonsil, the patient is induced to gag by a slight agitation of the points of the instruments; while the tonsils are thus protruded into the pharynx both loops are rapidly tightened and both tonsils are thus severed simultaneously. This form of double tonsillotomy has its advantages in dealing with timid patients as well as with timid parents or friends.

Where adhesions exist as a result of previous inflammation, frequently the results of cauterization, it is impracticable to remove both tonsils at once. In such cases the tonsil may require lifting with a sharp hook before the snare is applied. By means of the snare the tonsil is usually removed so perfectly that the stump is completely hidden behind the pillars of the fauces, the hemorrhage is slight, and the operation is free from danger.

The wire loop can be much more accurately adjusted in the average case for the removal of the tonsil than the tonsillitome. To insure the holding of the wire the stylet should fit the tube quite accurately, the grooves in its side being sufficient to receive the bent wire. No attempt should be made to remove a large tonsil with wire finer than No. 5, as it is liable to slip in the stylet.

I have never used a tonsillitome since I became familiar with this method, and I doubt if other practical men will if they become perfectly familiar with the use of the instrument. In all persons who will submit I inject the tonsil with five minims of a two per cent. solution of cocaine, in addition to applying the solution repeatedly to the surface.

In consideration of the ease with which the instrument is adjusted, the perfection with which it does its work, the reduced hemorrhage, and the absence of danger, this instrument is entitled, I believe, to the first place as a means of removing diseased tonsils.

The wound is frequently covered with a slightly white coating due to the sloughing of minute particles which have been pinched in the transit of the snare. Fever does not follow the operation, and to all appearances the cases recover quite as quickly as those operated upon by a cutting instrument. The momentary pain would appear to be greater with the snare. Patients who have been operated upon by both methods are in doubt regarding this question, and differ as to the amount of pain experienced.

In the extirpation of tonsils the rapid action of the instrument alone is used. Adenoids may be satisfactorily removed through the pharynx at a single sitting by this instrument, providing no part of the adenoid is anterior to a loop of wire which rests squarely against the posterior end of the nasal septum. In such cases the instrument must be used through the nose, with "a straight tip."

I am aware that exactly similar manipulations, of a very successful nature, have been made with the Jarvis snare. I believe, however, that experience will demonstrate that this instrument, with its firm handle and the further advantage of being quickly and powerfully manipulated with one hand, can be more advantageously placed and retained in the desired position for the successful removal of the growth, with less embarrassment from the faucial movements than any other snare with which the attempt has been made.

I have never seen an adenoid which, with this instrument, assisted slightly in very exceptional cases by an ordinary curette, cannot be removed with satisfactory results at a single sitting.

If the hearing of an individual has been reduced to two inches by catarrhal deafness, resulting from an adenoid, and the hearing is not improved by inflation, but is permanently cured by the removal of the adenoid, I think the growth has been removed with sufficient thoroughness. To produce these results the removal of these growths by the snare is sufficiently complete.

In support of the conclusion that adenoid growths which are quite cessile may be grasped with a snare, I call attention to the following case: A child, twelve years of age, had been etherized twice for the radical destruction of an adenoid by means of a curette. Three weeks later a wire loop was passed to the vault of the pharynx, and an adenoid the size of a hazel-nut was removed. This demonstrates that the radical destruction of adenoids under ether is not always a success as far as the removal of the growth is concerned.

I have a large number of similar cases, which illustrate the same facts, that I hope to publish in a future article on catarrhal deafness.

I feel fully convinced, from a careful perusal of Meyer's cases, that as a result of the many sittings required for the destruction of an adenoid with his ring-shaped knife, that he did not extirpate the growth as completely as we can now, with the snare, at one sitting. I have also many observations on record which show that the partial, or most imperfect, destruction of an adenoid has led to as satisfactory and permanent a restoration of hearing as the most perfect eradication of the growth could have done. I have one case where defective hearing was relieved, twenty years ago, by a dozen applications to a large adenoid of nitrate of silver fused on a probe. The adenoid was removed twenty years later by a snare, because of imperfect articulation which annoyed the patient in his professional calling as a lawyer. It is fair to conclude that if an adenoid is sufficiently removed to overcome difficulties of articulation, obstructive nasal breathing, and ear symptoms, that it has been adequately destroyed, and it is therefore unnecessary to resort to excessive manipulation in the naso-pharynx with cutting forceps, for there certainly is danger that excessive cicatrization in this position may lead to a hopeless catarrhal deafness. In the removal of all adenoids we will use the rapid action of the snare unless the hemorrhagic diathesis is known to exist.

In all forms of neoplasms and hypertrophies in the nostril or naso-pharynx where there is any suspicion of undue vascularity, the growth, after being firmly secured by the rapid action of the snare, should be divided very slowly by using the slow action of the instrument.

In the removal of nasal polypi the instrument has great advantage, as the action can be broken and the loop returned to position for further operation with great rapidity.

With a Graefe knife for the cartilagenous septum, a curette with a stiff copper shank, this snare, and a nasal saw having three inches of properly constructed teeth, not hampered by a probe-point, we are prepared to remove any bony deformity, benign neoplasm, or hypertrophy which is found in the nose, naso-pharynx, or pharynx. It can be done quite as quickly and quite as well as with the assistance of all the innumerable appliances at our command.

The instrument presented fully meets all the requirements met by Stoerk's laryngeal guillotine or wire écraseur, and furnishes the man not provided with an extensive assortment of laryngeal forceps with a simple means of reaching and extracting many of the foreign bodies which become lodged in and about the larynx.

To Remove Warts.—It is said that castor-oil applied for two to four or six weeks—that is, once a day—has not failed in any case.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 21, 1891, to June 27, 1891.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor. By direction of the Acting Secretary of War, is granted leave of absence for two months on surgeon's certificate of disability, with permission to leave the Department of Texas, and authority to enter the Army and Navy General Hospital, Hot Springs, Ark., for treatment therein, for a period of one month. S. O. 134, par. 12, Washington, D. C., June 12, 1891.

TAYLOR, BLAIR D., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect on or about the 14th proximo. S. O. 65, par. 3, Department of the Missouri, June 15, 1891.

MCKEE, JAMES C., Lieutenant-Colonel and Surgeon. Having been found incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, Revised Statutes. S. O. 137, par. 4, A. G. O., Washington, D. C., June 16, 1891.

BORDEN, WILLIAM C., Captain and Assistant Surgeon. By direction of the Secretary of War, will, upon the final abandonment of Fort Davis, Tex., report in person to the commanding officer at Jackson Barracks, La., for duty at that post. S. O. 139, par. 4, A. G. O., Washington, D. C., June 18, 1891.

PATZKI, JULIUS H., Major and Surgeon. By direction of the Acting Secretary of War, the leave of absence granted on surgeon's certificate of disability, in S. O. 99, May 1, 1891, from this office, is extended two months on surgeon's certificate of disability. S. O. 142, par. 15, A. G. O., Washington, D. C., June 22, 1891.

CARTER, EDWARD C., Assistant Surgeon. Relieved from duty at Fort Walla Walla, Wash., and assigned to duty at Fort Canby, Wash.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 27, 1891.

HALL, J. H., Surgeon. Detached from Naval Station, New London, and ordered to Naval Hospital, Chelsea, Mass.

ATLEE, L. W., Passed Assistant Surgeon. Detached from Nautical School-ship Saratoga, and wait orders.

STEELE, J. M., Passed Assistant Surgeon. Ordered to Nautical School-ship Saratoga.

LUNG, G. A., Assistant Surgeon. Ordered to Naval Station, New London, Conn.

PAGE, J. E., Assistant Surgeon. Detached from Naval Hospital, Mare Island, Cal., and ordered to the Independence.

PIGOTT, M. R., Assistant Surgeon. Detached from Receiving-ship Independence, and ordered to Naval Hospital, Mare Island, Cal.

FIELD, J. G., Assistant Surgeon. Detached from the Omaha, and granted three months' leave of absence.

BRATHWAITE, FREDERICK GRATTON, of Stamford, Conn. Commissioned an Assistant Surgeon, June 22, 1891.

RUTH, M. L., Surgeon. Detached from the Newark, and granted leave of absence for six months, with permission to leave the United States.

BRIGHT, GEORGE A., Surgeon. Ordered to the Newark.

PIGOTT, M. R., Assistant Surgeon. Ordered to the Receiving ship Independence.

WELLS, HOWARD, Surgeon. Detached from Naval Hospital, Chelsea, Mass., and to await orders.

STEELE, J. M., Passed Assistant Surgeon. Ordered to Naval Hospital, Chelsea, Mass.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 27, 1891.

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	9	7
Scarlet fever	131	24
Cerebro-spinal meningitis	0	0
Measles	244	20
Diphtheria	59	18
Small-pox	0	0
Varicella	9	0
Pertussis	0	5
Erysipelas	1	0
Mumps	0	0
Rötheln	0	0

The Lay of the Lymph.—The following appropriate lines have appeared in the *British Medical Journal:*

Who'll kill the bacillus?
"I," said Herr Koch,
"With my lymph and syringe,
I'll kill the bacillus."

Alas! Doctor Koch,
With false hopes you fill us;
For firm as a rock,
Holds the field—the bacillus.

And assembled bacilli
Through a cultur'd bacillus
Say, "We're not quite so silly
As to let Herr Koch kill us."

"Must admit," owns Herr Koch,
"I can't kill the bacillus,
Only cut off the stock
Of supplies from bacillus."

Replieth Herr Virchow,
"No lack of supply;
From one organ driven
To another he'll fly."

So some vow with a twinge,
"No more shall you drill us
With your lymph and syringe,
You can't starve the bacillus."

Arnica Eruption.—At a recent meeting of the Paris Biological Society, Dr. Dupuy related the case of a patient who was attacked by pseudo-erysipelas in consequence of an application of tincture of arnica. He regarded the fact as very curious, and remembered that essence of rue exerted a similar action.

Ringworm in Demand.—The following advertisement appeared the other day in a British paper: "Lady, having the care of two little boys with ringworm, wishes to meet with one or two others to share their educational advantages."

Disagreeable for the Doctor.—A physician of Chicago who was on the witness-stand testifying to the insanity of a man, was interrupted in his remarks by the landing of a rotten egg on his head. The egg was thrown by the subject of the doctor's testimony, who was promptly admitted to be insane, or at least "queer."

CONTAGIOUS DISEASES OF THE EYE; SOME STATISTICS, WITH REMARKS.[1]

By A. E. DAVIS, A.M., M.D.,

HOUSE SURGEON, MANHATTAN EYE AND EAR HOSPITAL.

MR. PRESIDENT AND GENTLEMEN: I have pleasure in reporting the statistics collected from something over one-half million eye patients treated in nine different eye and ear infirmaries in the United States of America. These statistics have been collected relative to contagious diseases especially, and coming as they do, at this opportune time, when the ophthalmologists[2] of New York City are urging the erection of a hospital for the treatment of contagious diseases of the eye alone, I am sure will prove of interest, and, I trust, of some assistance.

The nine institutions from which I have collected statistics are as follows:

1. Manhattan Eye and Ear Hospital (New York), twenty one years; eye patients treated, 76,103. Of this number

12,495	were	conjunctivitis	catarrhalis.
3,157	"	"	granulosa (trachoma).
485	"	"	" with pannus.
18	"	"	gonorrhœica.[3]
212	"	"	neonatorum.
446	"	"	purulenta or blennorrhœica and gonorrhœica.
1	was	"	crouposa.
17	were	"	diphtheritica.

2. Massachusetts Charitable Eye and Ear Infirmary (Boston), ten years; eye and ear patients treated, 84,228. Of this number

16,945	were	conjunctivitis	catarrhalis.
1,661	"	"	granulosa (trachoma).
730	"	"	" with pannus.
231	"	"	gonorrhœica.
303	"	"	neonatorum.
0	"	"	purulenta.
0	"	"	crouposa.
16	"	"	diphtheritica.

3. Eastern Dispensary (New York), four years; eye patients treated, 8,661. Of this number

2,038	were	conjunctivitis	catarrhalis.
617	"	"	granulosa (trachoma).
163	"	"	" with pannus.
4	"	"	gonorrhœica.
56	"	"	neonatorum.
0	"	"	purulenta.
0	"	"	crouposa.
0	"	"	diphtheritica.

4. Maine Eye and Ear Infirmary (Portland), five years; eye patients treated, 2,966. Of this number

197	were	conjunctivitis	catarrhalis.
28	"	"	granulosa (trachoma).
15	"	"	" with pannus.
5	"	"	gonorrhœica.
0	"	"	neonatorum.
0	"	"	purulenta.
0	"	"	crouposa.
1	was	"	diphtheritica

5. Illinois Charitable Eye and Ear Infirmary (Chicago), two years; eye patients treated, 8,906. Of this number

1,273	were	conjunctivitis	catarrhalis.
589	"	"	granulosa (trachoma).
342	"	"	" with pannus.
10	"	"	gonorrhœica.
17	"	"	neonatorum.
29	"	"	purulenta.
1	was	"	crouposa.
0	were	"	diphtheritica.

6. St. Mary's Hospital and Eye and Ear Infirmary (Detroit), one year; eye patients treated, 997. Of this number

70	were	conjunctivitis	catarrhalis.
38	"	"	granulosa (trachoma).
0	"	"	" with pannus.
0	"	"	gonorrhœica.
8	"	"	neonatorum.
6	"	"	purulenta.
0	"	"	crouposa.
0	"	"	diphtheritica.

7. Presbyterian Eye, Ear, and Throat Charity Hospital (Baltimore), twelve years; eye patients treated, 42,840. Of this number

1,796	were	conjunctivitis	catarrhalis.
377	"	"	granulosa (trachoma).
274	"	"	" with pannus.
0	"	"	gonorrhœica.
0	"	"	neonatorum.
482	"	"	purulenta.
13	"	"	crouposa.
9	"	"	diphtheritica.

8. New York Ophthalmic and Aural Institute (New York), twenty-one years; eye patients treated, 94,153. Of this number

23,656	were	conjunctivitis	catarrhalis.
5,111	"	"	granulosa (trachoma).
985	"	"	" with pannus.
126	"	"	gonorrhœica.
636	"	"	neonatorum.
0	"	"	purulenta.
20	"	"	crouposa.
135	"	"	diphtheritica.

9. New York Eye and Ear Infirmary (New York), last twenty-two years; eye patients treated, 192,923. Of this number

50,306	were	conjunctivitis	catarrhalis.
10,179	"	"	granulosa (trachoma).
1,184	"	"	" with pannus.
244	"	"	gonorrhœica.
1,142	"	"	neonatorum.
1,715	"	"	purulenta.
51	"	"	crouposa.
88	"	"	diphtheritica.

The number of eye patients treated in the nine institutions was over one-half million—to be exact, 511,807.

[1] Read before the Section in Ophthalmology of the New York Academy of Medicine, April 20, 1891.

[2] Dr. Callan, of this city, has been instrumental in having a bill pass the State Legislature for the erection of a special hospital for the care and treatment of contagious diseases of the eye, to be under the Health Department, but the medical officers to be nominated by the Council of the Academy of Medicine, New York, and appointed by the Mayor. The hospital to be situated in the city of New York.

[3] I wish to say that the eighteen cases of gonorrhœal ophthalmia here reported by no means represent the total number of gonorrhœal cases treated in the institution. The surgeons have not drawn distinct lines between purulent and gonorrhœal ophthalmias, but have classified most all purulent ophthalmias, whether due to a specific germ or not, as purulent ophthalmia when occurring in adults, and as ophthalmia neonatorum when occurring in infants. Hence this apparently small number of gonorrhœal ophthalmias reported.

Of this number 140,755 were contagious, furnishing 27.50 per cent. of the diseases of the eye. To recapitulate, I here subjoin a table showing the relative frequency of contagious diseases, and also the per cent. of all the diseases of the eye each furnishes.

	Number.	Contagious diseases.	All diseases.
		Per cent.	Per cent.
Contagious diseases	140,755	.....	27.50
Conjunctiva catarrhalis	108,778	77.28	21.25
Conjunctiva granulosa	21,757	15.46	4.25
Conjunctiva granulosa, with pannus	4,178	2.97	.82
Conjunctiva purulenta	2,678	1.90	.52
Conjunctiva neonatorum	2,374	1.69	.46
Conjunctiva gonorrhœica	638	.45	.12
Conjunctiva crouposa	86	.06	.017
Conjunctiva diphtheritica	266	.19	.052

From the tables of Cohn, thirty per cent. of the diseases of the eye are those of the conjunctiva, and most all of these are inflammatory and at the same time contagious. From the above tables we find that the contagious diseases of the conjunctiva furnish 27.50 per cent. of the diseases of the eye, which corresponds very closely to Cohn's tables; and when we remember that about two and one-half per cent. of the diseases of the conjunctiva are non contagious, it makes the two tables coincide exactly. Therefore we may take it as established that 27.50 per cent. of the diseases of the eye are contagious. It is interesting to note here the percentage of the cases of blindness furnished by contagious diseases of the eye. Quoting from the tables of Magnus ("Noyes's Text-book," p. 698) we find contagious diseases furnishing 25.72 per cent. of cases of incurable blindness in children under twenty years of age, and 20.72 per cent. of blindness in both adults and children; ophthalmia neonatorum alone, which furnishes but .46 per cent. of all diseases of the eye, furnishing 23.50 per cent. of the cases in children and 10.8 per cent. in adults and children; gonorrhœic ophthalmia and trachoma furnishing 1.81 per cent. of blindness in children and 9.49 per cent. in adults; diphtheritic conjunctivitis furnishing .44 per cent. of blindness in children and .35 per cent. in adults and children. It is thus observable from the foregoing tables that constituting 27.50 per cent. of all affections of this organ, the contagious diseases of the eye furnish 25.72 per cent. in children and 20.72 per cent. in both adults and children, of the incurable cases of blindness. This is a deplorable condition indeed, when we remember that ophthalmia neonatorum, as well as most of the contagious diseases of the eye, are, in a measure, preventable. Surely prophylaxis is our salvation in contagious eye diseases. And here that golden rule of surgery, "Cleanliness is godliness," should be most rigorously adhered to. Credé and Hausmann have found that by early antiseptic proceedings, both in the mother and child, the percentage of ophthalmia neonatorum cases are greatly reduced. Hausmann especially recommended keeping the vagina of the mother cleansed a few days before and during parturition with an antiseptic solution, while Credé dropped a single drop of a two per cent. solution of silver nitrate between the lids of the child immediately after birth. Credé reduced the number of cases in this way, in the Lying-in Hospital of Leipsic, from seven and one-half per cent. to .5 per cent.

As to the further treatment in these cases, I will go more into detail in the special statistics to follow.

Besides the foregoing general statistics I have, by the consent of the surgeons—Doctors Roosa, Webster, Pomeroy, and Emerson—collected the statistics of the last 38 contagious cases treated in the Manhattan Eye and Ear Hospital. Eighteen of these were treated for conjunctivitis gonorrhœica; 4 for conjunctivitis neonatorum, and 16 for purulent conjunctivitis—in all 38 cases. Of the 38 cases 23 were males, 15 females; 18 had both eyes affected, 22 one eye affected, making 58 eyes in the 38 cases. Seventeen of the cases were seen during the first week, the remainder any time from eight days to thirty days after the eyes were affected. Of the 58 eyes 22 had clear corneæ, 36 had either ulcerated, perforated, or sloughed corneæ. Out of the 22 eyes with clear corneæ 15 made perfect recovery without the cornea being implicated; 1 ulcerated, 4 perforated, 2 sloughed. The one that ulcerated obtained $\frac{20}{100}$ vision. Of the 4 that perforated 1 obtained $\frac{20}{30}$ vision; 1, $\frac{20}{70}$; 1, $\frac{30}{200}$; 1, perception of light. Of the 2 that sloughed, 1 perception of light; 1, nil. To recapitulate. Out of 22 eyes with clear corneæ 15 obtained perfect vision, 4 useful vision, 2 perception or light, and 1 only absolutely lost.

Of the 36 affected corneæ 20 had perforated, 9 had ulcerated, and 7 had sloughed. The 4 ophthalmia neonatorum cases furnished 3 of the eyes with affected corneæ—1 had an ulcer which left a slight opacity, the other 2 had perforating ulcers which left opacities with anterior synechiæ. The remaining 33 eyes with affected corneæ were in adults. Eight had ulcers, 18 perforation with anterior synechiæ, 7 had sloughs. Of the 8 eyes with ulcers 1 obtained vision $\frac{20}{10}$; 1, $\frac{20}{15}$; 1, $\frac{20}{30}$; 1, $\frac{20}{100}$; 1, $\frac{30}{200}$; 1, $\frac{18}{200}$; 1 fingers at eighteen inches; 1 perception of light. Of the 18 with perforations 12 obtained perception of light; 2, fingers at eighteen inches; 1, $\frac{6}{200}$; 1, $\frac{14}{200}$; 1, nil; 1, unstated. Of the 7 eyes with sloughed corneæ vision was nil, or 0, in all of them. We have therefore in the 36 eyes with affected corneæ 1 with perfect vision—$\frac{20}{15}$—in the case of a man with gonorrhœal ophthalmia contracted from acute gonorrhœa from which he was suffering at the time; 8 with useful vision; 3, fingers at eighteen inches; 13 with perception of light, and 8 with absolute failures. Three of the 36 eyes were ophthalmia neonatorum in children, above noted.

To recapitulate. Upon the 58 eyes treated for gonorrhœal ophthalmia, purulent ophthalmia, and ophthalmia neonatorum, perfect recovery resulted in 16 cases, or 27.59 per cent.; useful vision in 11 cases, or 18.96 per cent.; perception of light in 15 cases, or 25.86 per cent.; fingers in 3 cases, or 5.17 per cent.; opacities and synechiæ (in children) 3 cases, or 5.17 per cent.; absolute failure in 9 cases, or 15.52 per cent.; unstated in 1 case, or 1.73 per cent. The youngest subject—excepting the ophthalmia neonatorum cases—a boy, was seven years of age, and the oldest, a woman, sixty-five years of age.

Treatment.—The treatment in the ophthalmia neonatorum cases has consisted, to begin with, in protection to the well eye, if only one is affected. In a majority of the cases cleansing the affected eyes every fifteen to thirty minutes with a saturated solution of boracic acid, day and night, has been practised. And lately, and to this point I wish to call special attention, to keeping vaseline in abundance between the lids, even to filling the fornix, during the intervals of cleansing. At times very finely powdered boracic acid has been mixed with the vaseline, as Dr. Wilson,[1] of Bridgeport, Conn., who first proposed and used the remedy, suggested. Peroxide of hydrogen, full strength, dropped between the lids has been used to aid in cleansing all the pus from the eye that chanced to remain after using the saturated solution of boracic acid, and to good effect. However, it is well to be careful with this drug, as it is not altogether without danger where there is extensive ulceration of the cornea. Bichloride of mercury (1 to 5,000) has been used as a spray three times a day. In the later stages of the disease silver nitrate (ten grains to the ounce) has been applied with a camel's-hair brush to the everted lids once in twenty-four to forty-eight hours. Roosa advises strongly against silver in any form, save in the later stages of this disease. In corneal complications atropine (two grains to the ounce) and eserine (one grain to the ounce) have been used as indicated—the atropine when ulcer was at the centre of the cornea, and eserine when the ulcer was at the margin. Too much stress cannot be laid upon the importance of keeping the space between the lids and the

[1] Dr. Joseph A. Andrews, of New York, in the New York Medical Journal, October, 1885, recommended an ointment of vaseline and six per cent. boric acid for conjunctiva in purulent ophthalmias in the active stage, but soon abandoned it, save in the last stages of the disease.

fornix full of vaseline continually, for it acts not only mechanically as an emollient but as a protective to the corneal ulcers from germs.

The treatment in purulent ophthalmia in adults has been as varied as it has been unsatisfactory. First, protection to the fellow-eye by Buller's shield, or lint and plaster. Second, iced cloths continually to affected eye till pain is relieved, and afterward off and on often enough to control the pain and to aid in reducing the violent inflammation. Third, cleansing night and day every fifteen to twenty minutes with a saturated solution of boracic acid. Fourth, bichloride spray (1 to 5,000) three times a day. Fifth, vaseline between the lids, filling the fornix during the intervals of cleansing. (This has been practised since Dr. Wilson's first report of its beneficial effect.) Sixth, blue pyoctanin (one to two grains to the ounce) was tried in a few cases, but with no better results than those treated otherwise. Where there was great pressure on lids canthotomy was practised, and in a few cases where there was great chemosis of the ocular conjunctiva scarification of the œdematous conjunctiva. In no case has a vertical incision through the upper lid, as recommended by Critchett, been practised. Since Dr. Wilson's suggestion of vaseline between the lids as a treatment, it has been used largely in the Manhattan Eye and Ear Hospital, but in conjunction with other treatment. The percentage of recovery in these cases has been greater than those treated by any other method, but the cases have not been of sufficient number to give statistics upon. This method is employed by Drs. Emerson, Wilson, and F. W. Ring especially. In the later stages of the disease silver nitrate (ten to twenty grains to the ounce) has been applied with camel's-hair brush to lids once a day in some of the cases. In corneal complications atropine (two grains to the ounce) and eserine (one grain to the ounce) have been used, according to the location of the ulcer, as indicated. In some of the cases with very copious discharge, late in the disease, and with large corneal ulcers, hot water has been used to advantage. The results of this treatment are shown by the special statistics of the fifty-eight cases reported above.

I have, more especially for the benefit of students and general practitioners of medicine, added to the foregoing statistics a short review of the contagious inflammatory diseases of the eye.

In dealing with the different contagious diseases of the eye it will be well to remember that they cannot be considered as so many distinct processes, each confined to well defined limits and running a definite course, for there is neither sharply marked clinical nor pathological distinctions between the different processes in these diseases. In fact, following Meyer, "they must be regarded as different modifications of the same pathological process rather than as so many morbid entities." These modifications depend on various circumstances: on the general condition of patients, on immediate hygienic surroundings, on intensity and kind of inflammatory material, on intensity and duration of the process, and on the state of the tissues at the time of infection. Nor does it follow by any means that inoculation from one contagious disease will always produce that identical disease and nothing else—a catarrhal conjunctivitis producing a catarrhal conjunctivitis, and that alone, or a trachoma producing a trachoma, and only a trachoma. A simple catarrhal conjunctivitis may, and usually does, produce a catarrhal conjunctivitis, but it may produce a purulent or even a granular or diphtheritic conjunctivitis. This fact has been noted by different authors, from Stellwag, who in these diseases may be considered classic, down to the most recent authors. Stellwag[1] says "that a trachoma by no means always results from such a transferrence of the trachomatous secretion. On the other hand, again, the secretion of a pure catarrh or pure blennorrhœa, a urethral discharge brought in contact with the conjunctiva, may excite not only a blennorrhœa, but also a mixed or diffuse trachoma." But, to quote a more recent author, Meyer, we have this declaration in regard to the etiology of purulent ophthalmia: "What seems to be of more importance is, that the inoculation of the products of the secretion does not always produce the same form of the affection. We try to explain this fact by the varying condition of the soil which receives the infectious matter. Thus in one case of inoculation we see a simple catarrhal ophthalmia resulting; in another, a purulent conjunctivitis; and in a third, especially if the disease is epidemic, a diphtheritic ophthalmia."

I do not affirm but that a catarrhal conjunctivitis as a rule produces a catarrhal conjunctivitis, a trachoma a trachoma; yet I believe there are exceptions, many exceptions, to this rule, and that a catarrhal conjunctivitis may not only produce a catarrhal conjunctivitis, but also a purulent, a trachomatous, or even a diphtheritic conjunctivitis. And though Sattler, Neisser, and Wecks have found and isolated micrococci in trachoma, gonorrhœal ophthalmia, and catarrhal conjunctivitis ("pink-eye"), and have produced the same diseases from pure cultures of these germs, yet these observations have not been sufficiently confirmed by other observers; especially is this the case in regard to trachoma and pink eye. Schmidt-Rimpler could not find the diplococcus of Sattler and Michel. That most of the purulent and plastic inflammatory diseases of conjunctiva are due to a micrococcus there can be but little doubt, but that they are due to a distinct micrococcus there is some doubt; for if so, then the same distinct micrococcus must produce more than one disease, or in the production of one disease there must be more than one distinct micrococcus to have the present existing state of clinical facts which we have presented to us at the large clinics daily. We thus leave the etiology of these diseases in doubt. But to take them up briefly one at a time, we have to consider:

I. Catarrhal Conjunctivitis is a hyperæmia of the conjunctiva accompanied by a muco-purulent secretion, occurring in endemics and epidemics generally, and has a strong tendency to recovery. It may be idiopathic or symptomatic.

Pathology.—Anatomically it is a swelling and proliferation of the papillæ and epithelium of the ocular and palpebral conjunctiva.

Etiology.—Mechanical causes—as heat, light, smoke, dust, unhygienic surroundings, as in over-crowded tenement-houses, ill-ventilated and crowded charitable institutions and hospitals; locality—as seaside resorts, where there is heat, glare, and dampness, or on the plains from sand, heat and wind; symptomatic—as after the various exanthemata; contiguity of tissue—as from facial erysipelas, eczema, etc.; relaxation of tissue—as in old age; and by direct contagion, by transmission of specific germs into the eye, which seem in some cases to be communicable by the atmosphere.

Symptoms.—Hyperæmia and swelling of the conjunctiva, rise of temperature in severe cases, pain, photophobia, burning and sense of dryness of conjunctiva in the first stages, followed by muco-purulent secretion which glues the lids together in the morning. This secretion may become a purely purulent one. Finally, we have impairment of vision.

Diagnosis.—Mildness of the inflammation, as a rule; the fact that it occurs in endemics and epidemics, and in pink-eye by the microscopic examination of the secretion.

Treatment.—Place the patients in large, well-ventilated and lighted rooms, and especially, in hospitals and asylums, to keep them isolated from the remaining patients; cleansing often enough to keep clean; mild astringents, as saturated solution of boracic acid, alum wash (drachm to the pint), etc.; cold compresses in severe cases, nourishing diet.

Duration.—One to three weeks as a rule.

Prognosis.—Favorable. However, it may, and often does, produce acute trachoma, and not infrequently blennorrhœa or purulent conjunctivitis, with the attendant

[1] Text-book of Diseases of the Eye, p. 331.

evil effects, as entropion, ectropion, ulceration of cornea, pterygium, etc.

II. **Granular Conjunctivitis (Trachoma)** is, speaking in a comprehensive way, a hyperæmia of the conjunctiva, especially the palpebral and fornix conjunctiva of the eye, with swelling and hypertrophy of the epithelium and papillæ, and perhaps with formation of new granules (Belgian authorities). It is usually accompanied by a small amount of secretion, and in acute trachoma by free secretion; is of long duration and accompanied, in many cases, by Sattler's and Michel's diplococcus.

Pathology of Acute Trachoma.—Anatomically, swelling of epithelium and papillæ, with whitish, round granulations about the size of millet-seed, non-vascular in appearance and situated just below the level of the mucous membrane, between the swelled papillæ. There is also a serous infiltration in the conjunctiva.

Pathology of Chronic Trachoma.—In chronic trachoma we have three or four stages of the same pathological process, which for convenience of description and accurateness of portrayal we will follow the old classification of Stellwag and give in the following order: 1. Pure granular or follicular trachoma. 2. Papillary. 3. Mixed and diffused; the mixed being a combination of the pure granular and papillary, while the diffuse is only an advanced stage of the mixed, and should, I think, be described under the same heading.

Pure Granular Trachoma (Follicular — Meyer and Noyes) consists anatomically of semi-transparent, spawn-like follicles, situated chiefly in the fornix conjunctiva, with swelling of epithelium.

Papillary: Anatomically is hypertrophy of the papillæ and epithelium of the papillary conjunctiva, accompanied in advanced stages by serous infiltration around the swollen papillæ. It is a low form of inflammation characterized by a glistening white tarsal conjunctiva in the earlier stages studded over by very small semi-transparent granulations, disseminated in or arranged in rows upon the tarsal conjunctiva, and sometimes in the fornix or even upon the ocular conjunctiva at the angles of the eye. The anatomical nature of the follicles themselves is a disputed point, some claiming them to be true hyperplasia of the lymphatics of the conjunctiva, while the Belgian authorities in particular think they are a new formation altogether.

Mixed: Mixed trachoma, pathologically, is a combination of the above two, only here we have increase in the size of the granulations with a vascular plexus covering them. The conjunctiva is red and infiltrated, secreting a muco-purulent fluid, which, if it last a long time, causes a serous infiltration of the papillæ. Diffused trachoma is simply an advanced stage of the mixed variety, characterized by rough, fleshy formations upon the conjunctiva, formed by the blending of the old granulations with the swollen papillæ. However, not unfrequently, there is swelling of the lids and destruction of the cartilage in this affection. New granulations continue to form all the while.

Etiology of Acute Trachoma.—Direct contagion, unhygienic surroundings, injuries, catarrhal conjunctivitis.

Etiology of Chronic Trachoma.—Micrococci (the diplococcus of Sattler and Michel) unhygienic surroundings, acute trachoma, injuries, age (between twenty and forty being the most susceptible age, while youth and old age are much less liable).

Symptoms of Acute Trachoma.—Considerable swelling of lids, redness and injection of orbital and palpebral conjunctiva, swelling and redness of the papillæ, and interspersed between the papillæ are small whitish spots, which are true granules, and form the diagnostic symptoms of acute trachoma; muco-purulent secretion, which at first is scanty but becomes rather abundant in the second stage of the disease, and may become purulent in character; photophobia; pain in eye and forehead; impairment of vision.

Symptoms of Chronic Trachoma.—The symptoms in chronic trachoma are very mild at first. In fact the disease oftentimes creeps on unawares for months before the patient is aware of the fact of the serious nature of his affection. And that it is a serious affection cannot be too much emphasized. I once heard an eminent oculist say he had rather have a case of small-pox than a case of chronic trachoma, and I am not sure but that I share the same opinion. The first thing usually noticed is a sticking together of the lids upon rising in the morning, soon followed by a feeling as if sand was in the eye. Frequently there is a slight drooping of the upper lid, so that by this symptom alone we are sometimes able to diagnose trachoma before everting the lids. Vision is more or less impaired. Upon everting the lids we find a condition, according to the stage of the process, which we have already described above under granular or follicular conjunctivitis, papillary conjunctivitis, and mixed or diffused conjunctivitis.

Diagnosis of Acute Trachoma.—The small white spots or granules between the greatly swollen papillæ is pathognomonic, and when taken together with the swelling of the lids and the rather free secretion cannot easily be mistaken.

Diagnosis of Chronic Trachoma.—By long practice. History of the case.

Treatment of Acute Trachoma.—Is nearly wholly expectant, the thing most desired being to have just enough inflammation to cause a resorption of the granules. If the inflammatory process be very great, iced cloths to control it; if it assume the nature of a purulent ophthalmia, treat it as such; if it becomes chronic trachoma, treat it as a chronic trachoma. It must not be forgotten that spontaneous recovery sometimes takes place in these cases, occurring in those cases where there is just irritation enough to cause resorption of the granules. Cleansing with a saturated solution of boracic acid often enough to keep clean, and spray of bichloride of mercury (1 to 5,000) three times a day, is usually enough active treatment. Hygienic surroundings are important.

Treatment of Chronic Trachoma.—Granular or Follicular Trachoma may get well spontaneously also, but the manner in which this spontaneous recovery takes place is a disputed point, Noyes claiming, in trachoma with conspicuous lymphoid infiltration, that the superficial lymphoid follicles ulcerate and disappear in that way sometimes; while Stellwag asserts—long ago, to be sure—that they never disappear by ulceration or suppuration. Spontaneous recovery occurs most frequently in children. Follicular or pure granular conjunctivitis should never be treated by caustic or strong astringent applications, they do more harm than good. In the mild cases the lids everted and pencilled with a very mild solution of silver nitrate (two grains to the ounce), or touched with alum-stick three times weekly, may be practised with benefit. In severe cases where the follicles fill up the fornix, even forming folds, the remedy *par excellence* is to squeeze the lymphoid material out of the follicles with forceps—the most suitable forceps is that invented by Noyes. This causes considerable traumatism, and is to be followed by iced cloths and cleansing, and, after the reaction subsides, by pencilling the lids lightly with sulphate of copper crystal three or four times weekly. The duration of treatment altogether lasts from two to six weeks. This squeezing operation can be done either under cocaine (ten per cent. solution) applied by pledgets of cotton on the everted lids, or under ether. At the Manhattan Eye and Ear Hospital we always place the patient under the influence of ether. Noyes has reported one case of recurrence of the follicles after squeezing. Excision of the follicles, when very abundant, has been practised, but this, though a sure cure, is rather an extreme measure.

Papillary Trachoma. At Manhattan we find the local application to the lids with camel's-hair brush of bichloride of mercury (1 to 500 to 1 to 250) twice daily almost a specific. Where there is a scanty secretion sulphate of copper crystal touched to the lids, and pushed well up

into the fornix once a day, has been the sovereign remedy in the past, and is on every surgeon's cabinet yet, though we find that after a while it loses its effect and some other stimulant must be employed, as alum crystal, bichloride (1 to 250) painted on lids with brush, etc. Where the secretion is free, silver nitrate (ten to twenty grains to the ounce) painted on with camel's-hair brush, is a most useful remedy. Cleansing the eyes three times a day with bichloride spray (1 to 5,000) is good practice. Nutrition and hygienic surroundings are all-important in conjunction with the active treatment.

In trachoma with pannus, jequirity powder, made from the jequirity bean, dusted in the eye on the cornea and followed by iced cloths, is the favorite remedy practised at Manhattan Eye and Ear Hospital. It sets up inflammation similar to, but milder than, that caused by the secretion from acute gonorrhœa, forming membranes both on the lids and the cornea in the course of twenty-four to forty-eight hours, which separates from the lids and cornea taking with it the plexus of blood-vessels and swollen epithelium, in this way leaving the cornea clearer. Dr. Gruening, in severe cases of pannus, has recommended and practised scraping the cornea with a sharp knife. A very late treatment for papillary trachoma is incisions in the tarsal conjunctiva, extending even into the fornix, parallel to the free border of the lids, and each incision cauterized by a needle heated by electricity drawn from one end of the incision to the other.

Duration of Acute Trachoma.—Three to five weeks. When it runs its course in this time and terminates in recovery it is usually called Egyptian ophthalmia.

Duration of Chronic Trachoma.—One year to a lifetime.

Prognosis of Acute Trachoma.—Not very favorable.

Prognosis of Chronic Trachoma.—In follicular trachoma, by the latest modes of treatment, favorable. In papillary and mixed, unfavorable.

III. Purulent Conjunctivitis is a hyperæmia and swelling of the conjunctiva and lids of the eye accompanied by a copious purulent secretion in which, in gonorrhœal ophthalmia and ophthalmia neonatorum, is usually found the gonococcus of Neisser. Purulent conjunctivitis may properly be considered under three headings: First, Blennorrhœal conjunctivitis; second, gonorrhœal ophthalmia; third, ophthalmia neonatorum. The first, or simple blennorrhœal conjunctivitis, differs from catarrhal conjunctivitis only in degree of severity. The second and third are characterized usually by a micrococcus, the gonococcus of Neissier.

Pathology.—Anatomically same as that of a catarrhal conjunctivitis, only the epithelium and papillæ are much more swollen than in the former.

Etiology.— Unhygienic surroundings, inoculation by direct transmission of infectious material into the eye, as from specific urethritis or vaginitis, or even from a simple leucorrhœal or lochial discharge; catarrhal conjunctivitis, acute or chronic, and by metastasis.

Symptoms are those of acute catarrhal conjunctivitis much intensified; especially is this the case in regard to the secretion, chemosis, and swelling. The secretion at first is that of a muco-purulent type, but later in the disease becomes a purely purulent discharge and is very copious, even running over the lids on to the cheeks, and finally assumes a muco-purulent type a second time, as at the beginning. The swelling of the lids is very marked, causing the folds of the skin of the upper lid to be obliterated. The chemosis of the ocular conjunctiva in severe cases is very great, sometimes even overlapping the edges of the cornea. The epithelium and papillæ of the palpebral conjunctiva are greatly swollen and hypertrophied. The subjective symptoms are intense pain, photophobia, and in severe cases neuralgic pains in the temples and forehead. There may be febrile reaction in weak or nervous patients. When purulent ophthalmia is of a specific nature it is always more intense, and the mortality to the eye greater than when a simple blennorrhœa. As a rule the first eye infected is the worse. The second eye may become infected, though thoroughly protected, which can be explained only by a metastatic process first called attention to by Haltenhoff. In the metastatic cases the inflammation is very mild and of short duration. The period of incubation in gonorrhœal ophthalmia is about forty eight to seventy-two hours.

Diagnosis.—The great swelling and redness of lids, marked chemosis of ocular conjunctiva, and copious discharge of pus from eye over the cheeks, together with the history of the case and the aid of the microscope, make it easy of diagnosis.

Treatment.—The treatment in detail in purulent ophthalmia has been given in the special statistics of the fifty-eight cases of purulent ophthalmia reported above, and it would be only a repetition and loss of time to repeat it here.

IV. Phlyctenular Conjunctivitis is a hyperæmia of limited spots of the ocular conjunctiva, characterized by a serous or purulent exudation at these points, with elevation of the epithelium causing phlyctenulæ or blebs. Its chief characteristic is its tendency to recurrence. It occurs mostly in children.

Pathology.—Anatomically consists of local infiltrations of grayish nodules in the conjunctiva just beneath the epithelium, and later in the disease at these points there is an exudation of serous or purulent secretion beneath the epithelium, causing it to be raised up; enlargement and tortuosity of a limited number of blood-vessels of conjunctiva, which form a point at the bleb and spread out in the shape of the letter V from this point; destruction of the epithelium and ulceration at situation of bleb.

Etiology.—Age forms a great part in the production of this disease, it occurring chiefly in children, Meyer claiming that scrofulous children are no more liable to contract it than non-scrofulous, while Schmidt Rimpler and most modern writers think scrofulous children especially liable to it. Unhygienic surroundings also form a most important factor in producing this disease. Astigmatism has been brought forward as one cause by Mr. Martin, of Bordeaux. Finally, bad and improper food.

Symptoms.—The subjective symptoms are pain and burning of conjunctiva, together with a sense of dryness and photophobia. The objective symptoms, small, grayish nodules, vesicles, or pustules on the conjunctiva, with a strip of blood-vessels running from them. The vesicles may be large or small, and may be far from the cornea, or they may encroach upon it. The farther they are situated from the cornea the quicker they get well. These blebs or pustules have three stages. First, exudation; second, ulceration; third, healing. The general health of the child is, as a rule, in a poor condition.

Diagnosis is very simple; it only requires to separate the lids and make the observation of the phlyctenule.

Treatment.—Diet the patient; stop all tea and coffee, all sweetmeats, as candy, cakes, etc. Give milk, oatmeal, rice, hominy, potatoes, eggs, fresh meat once a day, and ripe fruit in limited amount. The yellow oxide of mercury (eight grains to the ounce) between the lids once a day is almost a specific when taken in conjunction with the diet. Calomel dusted into the eye once a day has been recommended highly, but no iodine should be given internally while the calomel is being dusted in the eye, as it is thought to form mercurial iodide, which is a caustic. It is doubtful, however, how the calomel acts, whether mechanically or as a bichloride. Vesicants, leeches, and strong caustics are never to be used. Strict hygienic surroundings should be insisted upon.

Duration.—From one to two weeks.

Prognosis.—Favorable. The only unfavorable factor being its tendency to recurrence.

V. Plastic Conjunctivitis may be considered under two headings, Croupous Conjunctivitis and Diphtheritic Conjunctivitis. The two varieties may be considered under the same head without impropriety, as they are different degrees of the same disease. The process may

involve only isolated spots of the conjunctiva, or it may involve the whole thickness of that membrane, becoming a true diphtheritic conjunctivitis, which is, however, a very rare occurrence, never occurring in newly born children. It is thought to be due to a distinct germ.

Pathology.—The ocular conjunctiva has in the beginning a large vascular net-work, pale in color, covering it, and there is at the same time a pale yellow chemosis, with apoplectic spots in the conjunctiva at times. The sub-conjunctival tissue is infiltrated, with coagulated fibrin. The palpebral conjunctiva is of the same color as the ocular conjunctiva, and so deeply infiltrated, in true diphtheritic cases, with fibrous exudation that most of the blood-supply is cut off, giving to the conjunctiva even a lardaceous appearance. In the croupous variety the exudation is limited to the surface, and often to isolated spots of the conjunctiva, and is not infiltrated deeply into the substance proper, being easily rubbed off; while in the true diphtheritic variety the infiltration is deep, involving the whole thickness of the membrane, and cannot be removed. There is compression of the blood-vessels in the true diphtheritic form, due to the infiltration of coagulated fibrin into the tissues.

Etiology.—Micro-organisms; direct transmission of infectious material from one eye to another; injuries; caustics; contiguity of tissue; vaginal secretion from mother in childbirth (Stellwag); while, interesting to relate, Meyer claims that diphtheritic conjunctivitis never occurs in new born children. This disease usually occurs in epidemics and is a local manifestation of a general disease. It may occur in a protected eye by metastasis. In this place a quotation from Meyer ("Text-Book," p. 823) will not be amiss. He says: "Although the diphtheritic disease is eminently contagious it must be kept in mind that inoculation does not produce always the same disease, but perhaps a catarrhal or purulent affection of the conjunctiva; while, on the other hand, inoculation of purulent matter may produce diphtheritic conjunctivitis." Another important and interesting fact in the etiology of plastic conjunctivitis is, that inflammations of mucous membrane are most rarely accompanied by fibrous exudations, and when it does occur it is absolutely necessary to have a break or excoriation of the epithelium of the conjunctiva to have a plastic exudation.

Symptoms.—In the beginning of this disease we have, as subjective symptoms, heat, pain, photophobia. As objective symptoms, swelling and stiffness of the lids, with a rose-colored blush of the outer surfaces, patches of membrane of a grayish dirty color, which can be easily removed in the croupous variety, but cannot be in the diphtheritic conjunctivitis proper, this being a diagnostic point between the two. There is more or less discharge from the eye, composed of flakes of membrane and epithelium floating in tears, and a muco-purulent secretion. In five to ten days the secretion changes to a purulent nature, but still has masses of coagulated fibrin floating in it, the swelling decreases and the lids become less stiff and lose their leathery feel. The vessels reappear on the conjunctiva, and patches of the membrane come away *en masse*, leaving the conjunctiva denuded, which becomes covered with papillary excrescences, and the disease assumes the form of a true purulent conjunctivitis. The yellow color of the conjunctiva disappears at the same time. If the cornea becomes affected early in the disease it will almost certainly slough and the eye be lost. The later it is affected, as in the other contagious diseases of the eye, the better the chance for the recovery of the eye. During the healing process cicatrices often form between the ocular and palpebral conjunctiva, binding them together. Even xerophthalmia may occur. The longer the first stage the shorter the second, and *vice versa*.

Diagnosis.—The stiff, leathery feeling of lid, with a rose-tinted blush, together with the membrane on conjunctiva (palpebral), and oftentimes with diphtheritic spots in nose or throat, and the history of the case, are sufficient to establish a diagnosis.

Treatment.—Protection to opposite eye and to attendants. Antiphlogistics, as iced cloths and cold compresses in the earlier stages. Mild astringents. Bichloride of mercury as a spray four times daily, cleansing with saturated solution of boracic acid sufficiently often to keep eye clean. Silver nitrate has been recommended in the purulent stage by some authors, but I think it very bad practice, as we know that the nitrate of silver can, and does sometimes, produce a membranous conjunctivitis. Quinine in small doses has been strongly recommended. Treat the general condition with nourishing food and stimulants.

Duration.—Three to eight weeks.

Prognosis.—In croupous conjunctivitis favorable, in the true diphtheritic conjunctivitis the most unfavorable of any contagious disease of the eye.

THE THERMAL WATERS OF NEUENAHR.

By PAUL UNSCHULD, M.D.,
RESIDENT PHYSICIAN OF THE PLACE.

The writer of these lines begs pardon for venturing to bring under the notice of American readers some particulars of a watering-place which already ranks among the famous spas of Europe.

Neuenahr lies on a tributary of the Rhine, in the valley of the Ahr, at an elevation of 86.60 metres above the level of the sea. Neuenahr is surrounded by ranges of hills, rising to the height of 400 metres, which for miles are covered with woods. Two conical basalt peaks, crowned with the ruins of old castles, stand like watchmen on either side of the place. The climate is mild (mean yearly temperature being 51°, that of the summer months being 65.1° F.) and is free from sudden changes; the atmosphere is moderately dry, uncommonly pure, and rich in ozone—all those factors which pollute the air in towns and industrial countries being absent. This renders Neuenahr particularly suitable as a place for treatment to those who, by dint of overwork, or being overtaxed in their mental or emotional powers, require relaxation and strengthening of their whole nervous system. For such patients even our lovely country offers a factor of health. The romantic beauty of the Rhine is famed throughout the world, and our vale of the Ahr is the brightest jewel in the crown of the Rhine. Our valley can boast, too, of some historical fame. The brave race of the Treviri reigned here, and to those who have read Walter Scott's novel, "Quentin Durward," it may not be uninteresting to know that the Wild Boar of the Ardennes, William de la Marck, belonged to our nobility. Also the founder of the cathedral of Cologne, Archbishop Hochstaden, was a native of Neuenahr. The minister von Stein, who in the beginning of this century prepared the way for Bismarck, was the possessor of Landscron castle.

But more interesting to us are the healing powers of our thermal springs, which may be compared with those of Vichy, Carlsbad, and Ems. These four alkaline springs are, in fact, the only warm alkaline ones we have. Their chief constituents consist of bicarbonate of soda, sulphate of soda, carbonate of magnesia, bicarbonate of lime, chloride of sodium, a small quantity of lithia, and iron. Carbonic acid is more abundant than in Carlsbad and Vichy. The names of the springs are: Kleiner Sprudel, 14° C. (not used for drinking); Augusta Quelle, 27° C. (with little carbonic acid); Victoria Quelle, 27° C. (with more carbonic acid), and Grosse Sprudel, 37° C. (richly impregnated with carbonic acid). The amount of carbonic acid escaping from the incessantly bubbling and seething waters some days rises to such a degree that it is dangerous even for man to approach, and other living beings which may come into the reach of this exhalation are often seen to fall down dead. With regard to the salutary effects of our thermal springs the same indications and contra-indications may be given, on the whole,

for them as for other alkaline wells, yet, it may be permitted to mention the diseases in combating of which Neuenahr has proved especially efficacious.

The best results are obtained in the various complaints of the stomach. Carlsbad, Marienbad, Franzensbad, and Bohitsch are generally placed before Neuenahr as watering-places in these cases; but, without considering that any mineral-water cure has to be regulated according to the effects on the chemical action of the stomach, there are especial indications in question for each particular place. Above all I give weight to the degree of heat in the waters. In cases of nervous dyspepsia, atony, and hyperacidity, the sensation of thirst is generally increased. This symptom is speedily removed by the use of a warm mineral water. Warm water is easily taken in by the stomach and quickly absorbed. The greater the quantity of water taken in a short time, the nearer its temperature must be to the warmth of the blood. The waters of cold springs are therefore artificially heated before being taken. The waters of Neuenahr have the suitable temperature, the very warmth of the blood. This is the reason for their good effect in the treatment of simple and chronic catarrhs of the stomach, also in that of chronic ulceration.

At the Congress of Physicians, in the spring of 1888, the author of these lines delivered a lecture on this subject, quoting, among other interesting cases, one in particular of a lady who, having been suffering for twenty-five years, having passed from one infirmary to another without relief, had become addicted to morphine. Her medical adviser thought her afflicted with carcinoma. She could not retain any food, she repeatedly had violent vomiting of blood, and was quite emaciated and drawn together with pain; indeed she bore the aspect of one hoplessly lost. Her cure at Neuenahr was no sudden one, it required many months before she recovered, but then she was quite restored, and is now, after the lapse of many years, living in good health at Arnheim. It is easy to conceive that alkaline waters must act favorably in cases of ulcer of the stomach, for, according to our most modern inquiries, the ulcer in the stomach is the secondary and the hyperacidity the primary condition. Hemorrhage of the stomach, also, is believed to be due to excessive acidity. An addition of bicarbonate of soda to the thermal water forwards the effect, and its use is not in the least objectionable in cases of hemorrhage of the stomach.

A second group of diseases of the stomach which we treat with success are the neurasthenic forms and atonia ventriculi. The latter complaint appears very frequently in the present age, and is marked by its numerous complicated symptoms, by its tenacity, and the final issue in anæmia, enervation, and loss of flesh. Now Neuenahr acts in divers ways: 1, By correcting the hyperacidity, which is always present in atonic cases; 2, by relieving insomnia, through the perfect stillness which reigns here and the large amount of ozone in the air, abstinence of mental excitement, through free bodily exercise in our lovely vales and hills, and through the manifold means offered in the various kinds of baths, as well as in the hydrotherapeutic, electric, and dietary treatment.

It is indeed surprising to behold how such patients, having suffered for months, ay, years, having in vain tried various methods of treatment, after but a short stay in this place experience relief, regain appetite, increase in weight, and regain their former vigor of mind.

In affections of the liver and gall-stones Neuenahr is not less effective than Carlsbad, and those who have not been eased or cured in Neuenahr will not find relief in Carlsbad. It was only last summer I was treating here a gentleman who had been suffering from violent attacks of biliary colic; he returned home quite cured, after having passed above a hundred gall-stones. The explanation of this effect most probably lies in the increased alkalescence of the blood produced by the abundant use of our alkaline wells, by which a greater quantity of alkaline bile is secreted, capable of dissolving the concretions, and, by diminishing their size, rendering it more easy to expel them.

I need not enlarge on the effects of our waters with regard to catarrhs of the mucous membrane, diseases of the kidneys and bladder, as well as affections of the uterus; for that warm alkaline waters are generally advantageous in all catarrhal states of the body is everywhere acknowledged

There remain to be mentioned, in particular, chronic rheumatism and gout. General opinion is in favor of alkaline mineral waters as the best medicament against gout, and Dr. Pfeiffer, at the Eighth Congress for Internal Medicine, in 1889, most clearly and convincingly proved this. Contrary to the present prevailing opinion he considers lithium to be indifferent in this disease. Experimenting, Dr. Pfeiffer found that after bathing for twenty days successively in Kochbrunnen (27.30° R.) the daily secretion of uric acid in the case of gouty patients was always considerably lessened; in most cases it was reduced one-half, in a few even only traces were left. Therefore, not only a rational internal use of alkaline waters, but also their employment in the form of baths, must be regarded as an important means to remove the uric acid diathesis. Neuenahr may boast of excellent results in cases of gout. Of course the manner of life and diet have to be regulated by the prescribed regimen. Nor can the cure be reckoned by days, but it will require a yearly repetition, and, may be, the taking of the Neuenahr waters in the time between.

Of late Neuenahr has gained great reputation, and even become a rival to Carlsbad in cases of diabetes mellitus. Every year more persons similarly afflicted resort hither, even those who formerly went to Carlsbad. The reason thereof is said to be that Carlsbad weakens too much, but that Neuenahr excites and invigorates. Without pretending to defend the truth of this statement, experience warrants me in holding that, in most cases, the secretion of sugar is diminished or stopped.

We do not pretend that these waters are a specific in all cases of diabetes. The most that can be done by any therapeutic measure in the majority of cases of this disease is to moderate its course and to raise the general tone of health and vigor, to stop the progress of the disease and delay the final result as long as possible.

A constant repetition of the treatment is advisable. In fact, we have already a pretty large number of diabetics who habitually frequent this place. And if we grant that the science of healing is able to prolong the life of the sick, undoubtedly it is here the case with diabetes, often even to the natural term of life. Frerichs, in his essay on diabetes, says, "the alkaline waters of Carlsbad, Neuenahr, and Vichy, in the treatment of this disease, are of much greater value than the simple carbonate of soda. My large experiences leave me no doubt that by the use of these waters the diabetic disturbances will be soon either quite removed, even if only for a certain time, or at least considerably lessened."

I beg leave to add that my own experience, embracing many hundreds of cases, makes me certain as to the favorable influence of the waters on the course of this disease.

During last summer Neuenahr was visited by 5,458 patients, among them 64 Americans.

The place possesses many climatic advantages compared with Carlsbad and the other warm alkaline springs. With the charms and quiet of country life it combines the comforts of an excellent Curhaus and other good hotels, as well as eating houses, cafés, restaurants, and private lodging-houses. For Americans I can recommend Villa Humboldt. There are shady walks and very fine extensive grounds, and the bathing establishment will satisfy all balneological demands. The religious wants of the different confessions are duly attended to. Daily concerts, frequent evening parties, and a theatre during the season, bring change and solace to the visitors.

Trains starting from Bremen and Hamburg reach Neuenahr in ten to eleven hours; from Antwerp, Flushing, Rotterdam, in about seven hours.

THE TREATMENT OF RETRO-DISPLACEMENT OF THE UTERUS, WITH ADHESION, BY BRANDT'S METHOD.

By H. N. VINEBERG, M.D.,

NEW YORK.

In a short paper published in the New York *Medical Journal* for January 24, 1891, I gave a sketch of the origin and history of Brandt's system, and the impressions and observations gained during a stay of several weeks in Stockholm. I purposely refrained from any attempt at describing the method, because, as I stated in the paper, it was my belief that the various manipulations could be learned only from practical instruction, and not from descriptions, no matter how elaborate. But as many who are interested in this subject have found fault with the course I followed, and have expressed a desire to know more in detail about the method, it will be my aim in this communication to describe, as briefly and as clearly as I know how, the several manipulations Brandt employs for the cure of the different forms of backward displacements of the uterus with adhesions of varying degree. Although I do not underestimate the value of the numerous Swedish movements Brandt practises in addition to the special massage, and upon which he lays great stress, I will not dwell upon them in this paper. My reasons for this are: 1, Because, in my opinion, they can in a measure be substituted by exercise, such as walking and riding; and 2, because in this country, as yet, it would be impracticable even for the specialist to carry them out, calling as they do for a trained assistant and for time, patience, and expense on the part of the patient. Even when the general movements are ignored, doubtless the chief obstacles Brandt's method will encounter in its adoption by the specialist here are the time it consumes and the hard physical labor it involves on the part of the physician. These are considerations, however, which in these days of specialism ought not to carry any weight. On the contrary, they should be welcomed by the specialist, for they form the chief and most plausible argument for the *raison d'être* of his existence. The day is passing when the attainments of a gynecologist, in the fuller sense of the term, are limited to a carpenter-like dexterity, a sharp knife, and antiseptics, as wittily remarked by an eminent physician; for gynecology is making rapid strides toward the goal long ago reached by a kindred branch surgery, which saw in the new field opened up by antisepsis, not an opportunity for more reckless cutting, but for more conservative methods. The surgeon now no longer boasts of the number of limbs he has amputated, but of the number he has saved; he does not remove a kidney which he can save by cutting into and removing the diseased or foreign substance, and he does not excise an ankylosed joint when he can render it supple and useful by massage. In the same way the gynecologist in the near future will be proud of the number of ovaries he has saved, and not of those he has removed; he will aim at freeing an adherent uterus rather than fixing it in a different position, and he will try to strengthen the uterine supports rather than shelve the uterus upon an artificially made one or impale it upon a pessary. It seems to me that every new method in gynecology which has some promise in it should not be looked upon with the jealous eye of a rival. We should, on the contrary, greet it as a kind coadjutor whose powers to aid us in the perplexing problem of cure we are willing to test with friendly feelings free from prejudice or bias. After electricity has done all it can, after massage has accomplished all that can be reasonably expected from it, there will always remain a goodly number of cases over which the knife will hold its sway. The excuse for the resort to the knife has always been, excepting in cases of collections of pus and malignant disease, that "everything" had been tried and failed. But the "everything" on being analyzed was usually found to consist in painting iodine to the vault, introducing glycerine or boroglyceride tampons in the vagina, and the employment of hot vaginal douches, usually imperfectly carried out. Let us hope that this opprobrium to the gynecologists' "everything" will be removed with the enrichment of pelvic massage and electricity to their armamentarium. It was thoughts similar to those expressed above that induced me last summer to go to Stockholm and Paris and make observations for myself. What those were that I made in Stockholm I have already put on record, and I need not repeat myself here.

To begin with the subject before us. It is pretty generally conceded that the treatment heretofore in vogue for backward displacements of the uterus, with adhesions, has been in the main unsatisfactory. The number of ingenious operations constantly devised for their relief is sufficient evidence of this. Many of these operations are difficult to perform, and in spite of improved technique and careful antisepsis they are not entirely free from danger. The sequelæ which sometimes follow them are worse than the disease for which they were done. The woman may now have, in addition to a fixed uterus, a stricture or obstruction of the bowels due to adhesions. But in pelvic massage and systematic stretching, on the other hand, we have a remedy which in careful hands is not only free from danger, but is the only true means that we possess of restoring the parts to their normal condition. Even when it fails to do this, it brings about a condition essential for the success of any operative procedure that may afterward be undertaken. Given a case of backward displacement, it is only rarely that the abnormal position of itself gives rise to any trouble. It is usually the adhesions, the shortened and thickened ligaments, and the new formations of cord-like tissue that cause the woman her aches and pains, and other symptoms for which she seeks the physician's aid. How true this is any one may prove for himself by recalling the very small number of simple uncomplicated displacements for which he has been consulted, say for the period of the past twelve months. A further proof is found in the fact that as soon as the uterus is freed from its adhesions all the symptoms almost invariably vanish, although the uterus may still retain the same faulty position as before.

Schultze was among the first to bring this clinical fact before the profession, and was the first, I believe, to show that a fixation of itself may constitute a displacement. A uterus may lie in ideal anteversion, but if its movements are restricted by perimetric adhesions or cicatricial bands its position is justly considered faulty, and the term displacement characterizes it.

Before we can make any attempt at replacing a uterus the adhesions must be gradually broken up and the cord-like bands and cicatricial tissue must be subjected to systematic stretching. The amount of force to be used in accomplishing this will necessarily vary with each case, and is dependent upon the firmness of the organized membranes and the sensations of the patient. While it may frequently be impossible to achieve much without causing some pain to the woman, the causation of any great degree of pain must be desisted from. The degree of pain evoked is not, however, a safe criterion as to the amount of force we may safely employ. For, as it is well known, many women are so sensitive that they will cry out with pain on the slightest touch, while others are so insensitive, or can control their feelings so well, that a dangerous amount of force might be used before a cry or wince would be elicited. A certain amount of tenderness is no contra-indication against stretching. Were this the case pelvic massage would have but a limited field. But any subacute process indicated by an elevation of temperature is an absolute contra-indication. So would also be unmistakable purulent salpingitis. In the em

ployment of stretching it is extremely important to keep in mind the condition of the tubes and ovaries. When chronic oöphoritis and catarrhal salpingitis, with adhesions, co-exist, the greatest caution must be exercised for fear of lighting up an acute attack. Under all conditions one must begin cautiously. "Better do little than too much at one sitting," is an oft-repeated injunction of Brandt's not to be ignored with impunity. One should never under any circumstance use such an amount of force as to tear an organized membrane and rupture a blood-vessel, which would be followed with the invariable result of a pelvic hæmatocele or inflammatory exudation. If one goes to work carefully at first, it will not be long before he will acquire, so to speak, an intuitive sense as to the degree of force he may employ with safety in a given case. Brandt lays down the rule that the stretching should only be continued as long as it is felt that the elasticity of the tissues yields to the force employed. Any stretching beyond this is certain to result in rupture of the tissues.

In order to carry out the stretching the patient is placed in the usual position for pelvic massage. That is, she lies in a modified lithotomy position on a short, low couch which is firmly upholstered, and possesses a movable head-piece which is placed at an angle of about seventy-five degrees to the surface of the couch. The patient's head and shoulders rest on the head piece, and thus the greatest relaxation possible of the abdominal walls is obtained. The corsets are removed and the clothes are loosened, and every precaution taken not to unnecessarily expose the patient. The operator sits at the left side, near the lower end of the couch, with his knees widely separated so that the inner surface of the right knee rests against the left side of the couch—the left knee and lower third of the thigh embraces its left lower end. The operator's left knee serves the double purpose of giving support to his left elbow, and of preventing the patient from slipping down. The patient is brought well over to the side of the couch so that the operator is not constrained in his work. After anointing the left index-finger with vaseline (or it and the middle finger if the operator has rather small and short fingers) it is carried into the vagina under the left thigh at a moment when the patient is told to lift up her left leg. In this way soiling of the under-garments is avoided. The remaining three fingers of the left hand being left open rest on the perineum, and the thumb is held in wide abduction so as not to come into contact with the pubes. The stretching is chiefly done with the vaginal finger, aided by the right hand through the abdominal walls. The finger picks out the cord or ligament, makes it tense by pressing up against it, and the external hand tries to meet it and assist in stretching it. While the cord is still kept tense with the vaginal finger the external hand *massées* it, annulling the sensitiveness, and rendering it more flexible and yielding. Then an effort at stretching is made again, and thus the massage and stretching are done alternately, until we have accomplished as much as we may with safety at one sitting. Flaky adhesions are separated by the vaginal finger being placed against the point of adhesion, and the fingers of the external hand are made to peel the uterus away from the adhesions. When feasible the adhesions are stretched by catching the fundus between the vaginal finger and external hand and pulling it gently and steadily in a direction opposite to that of the adhesions. This manœuvre is easily executed in lateral fixations which frequently complicate posterior displacements. In some cases when the adhesions are situated high up, and in others with a deep vagina, the stretching can best be done with the patient in the standing posture, for then the pelvic contents naturally sink lower down. Sometimes it is possible to reach further up with the finger in the rectum than in the vagina, especially if the thumb is introduced in the vagina. This position of the fingers of the left hand is preferable in a number of cases, even when the fixation is low down. By it the bands and restricting cords are frequently picked out with greater ease, and put on the stretch. In some cases when both of the above manipulations have failed I have succeeded by seizing hold of the cervix with a volsellum and gently drawing the uterus down to near the entrance of the vagina. But of this again when treating of replacement. When the stretching is done through the rectum one must guard against the common error of merely pushing the rectal wall forward instead of actually distending the adhesions. The stretchings are always preceded by *massée-ing* the abdomen in the region of the umbilicus and going downward until the uterus is reached. This procedure pushes the intestines out of the way and opens up the large lymph duct. When the uterus is used as a handle in stretching the adhesions, it is always advisable to first *massée* it thoroughly, which has the effect of rendering it less sensitive. A good practical point inculcated by Brandt is that the pressure should not be applied at the centre of the fundus, which is very sensitive, but at either side, which is much less sensitive. One can easily convince himself of the value of this suggestion. In fact Brandt's teachings are full of such valuable practical points, which bespeak careful and accurate observation and an enormous experience. At the conclusion of the *séance* the abdomen is *masséed* in a direction just the opposite to that at the commencement. Finally, the operator's hand is allowed to rest flat on the patient's abdomen, and a slight trembling movement may be carried out so as to annul any pain the treatment may have caused. Brandt recommends for this purpose, in addition, pressure against the pudendal nerve, carried out by applying the thumb on either side of the anal opening toward the tuber ischii. Before the patient is allowed to change her position on the couch "knee adduction" is performed three or four times. The patient is told to elevate her hips and bring her heels close together so that she rests on her shoulders and feet. The knees are separated wide by the patient, and are brought together by the operator by placing a hand on each knee at its outer side, while the patient exercises moderate and steady resistance. The operator then draws the knees apart, also under the patient's resistance. By a little reflection it will be seen that in both movements it is the abductors that are brought into action. This has a derivative effect on the contents of the pelves by drawing the blood away from them, and thus lessening any congestion that may have been caused by the treatment. When we have succeeded in distending the bands and cords, and have broken up the flaky adhesions to such an extent that the uterus is fairly movable, we begin with our attempts at replacement. Brandt employs for this purpose six different manipulations which may be characterized as follows: 1, Leverage; 2, wedging; 3, hooking; 4, reduction pressure; 5, "reduction with one finger;" 6, ventro-vagino-rectal reduction.

1. Leverage can be used only when the uterus is small and rigid, so that when pressure is made against the cervix backward, the fundus is thrown forward and can be seized with the external hand through the abdominal wall, and brought into the normal position.

2. Wedging is resorted to when the uterus lies flat against the pelvis and cannot be replaced by leverage. It is performed by pressing gently the fingers of the right hand through the abdominal walls to the upper border of the fundus, and letting them lie in wait there until the moment the pressure of the vaginal finger succeeds in displacing the uterus slightly forward, then by a quick movement they are wedged in, so to speak, behind the fundus and pull it forward in the usual bimanual manner.

3. Hooking is performed when the uterus is very soft and flexible, so that the first and second cannot succeed. The effort is made to get behind the fundus with the vaginal finger along either angle of the body, and to tilt the fundus forward; the fingers of the external hand are then hooked behind the right tubal angle, and in this way the uterus is drawn forward.

4. Reduction pressure is resorted to when the cervix is fixed anteriorly and the uterus lies low down in Douglas's cul-de-sac. It is performed as follows: The vaginal finger is placed against the fundus and presses it forward, and the external hand is placed just above the symphysis and deep pressure is made backward toward the sacrum. After a time the vaginal finger is carried anteriorly to the cervix, preferably to the middle of the vaginal portion. Now both the internal and external fingers are simultaneously pushing against the cervix toward the sacrum. This usually succeeds in flexing the uterus somewhat forward. The vaginal finger is still held in the same position, pushing the cervix backward, while the external fingers are carried gently along the sides of the uterus to the upper border of the fundus, behind which they are made to insinuate themselves, and the fundus then is carried forward toward the symphysis.

5. Reduction with one finger is more an evidence of Brandt's dexterity than an essential of his technique. He carries the fundus as high as possible with the index-finger in the vagina, and then by a clever movement he twists the lower part of the finger around to the anterior surface of the cervix, still supporting the fundus with the point of his finger. He now withdraws the finger slightly and applies its point in front of the vaginal portion, which he pushes as far upward and backward as possible, thus throwing the fundus in the forward position.

6. Ventro-vagino-rectal reduction is resorted to when the fundus is too high to be within the reach of the finger in the vagina. To execute this manipulation the index-finger is passed high up in the rectum by pushing up the perineum as far as possible, the thumb is then inserted into the vagina, serving the double purpose of pushing the cervix backward, and of permitting a higher introduction of the index-finger in the rectum. The index-finger tries to dislocate the uterus and presses the fundus forward, while the external hand endeavors to seize it and bring it forward in the usual manner.

In these various manipulations for replacement it does not infrequently happen that they fail because the fundus is pushed up against the promontory. This contingency may sometimes be avoided by pushing the fundus to one or either side, or by a skilful use of the external hand in pressing the pelvic contents downward and forward. If these manœuvres fail, as they will sometimes, an attempt should be made with the patient in the knee-elbow or the Sims position, or with the patient lying on her face. Should failure attend all these, the uterus may be drawn down gently to near the entrance of the vagina by seizing hold of the cervix with a volsellum. But this unfortunately necessitates the aid of an assistant. I have succeeded, however, in carrying this out in one case without any assistance. In the absence of an assistant, however, the corrugated tenaculum described by Dr. Howard Kelly in the *American Journal of Obstetrics and Diseases of Women and Children* for February, 1891, might be of service. The traction, if done carefully, can only be of benefit in that the restricting bands and ligaments will be subjected to stretching which would be of difficult execution with the finger owing to their very high situation.

I am well aware that most of these manipulations for the replacement of a retro-placed uterus have been employed by gynecologists for some time past, and I had used some of them myself long before I had heard of Brandt's work. But to Brandt is due the credit of elaborating and classifying them, and of showing the much greater value and safety of making repeated daily attempts, over the usual method of trying to accomplish all at one sitting. This may appear but a simple matter. But it is just to such simple matters as this that the science of gynecology owes its greatest advancement. Once the uterus has been freed from its adhesions so that it can be replaced to its normal position, Brandt begins his "lifting" process. The "liftings" innervate the uterine attachments, and stimulate them to contraction so that they will retain the replaced uterus permanently. Time and space will not allow me to describe this somewhat complicated manœuvre which the beginner finds so extremely difficult to perform. It certainly cannot be learned from descriptions, even with the aid of drawings. Even under the guidance of the master himself the tyro will fail several times before he meets with success once. As it is a procedure capable of making matters only worse unless properly carried out, I would advise those who cannot receive practical instruction to leave it entirely alone. Of course in adopting a new method, the proper and scientific course is to follow the originator precisely in every detail. When this has been done, and the pupil is master of the situation, and is desirous of simplifying the method he may do so by leaving out a manipulation now and then, and observing if the results remain the same. Another course, less commendable, is as Ziegenspeek has stated, to begin with the smallest number of the manipulations, and keep adding one detail after another until the same results are obtained as when every detail is followed. To follow this course requires great honesty and deeper powers of observation than I think most of us possess. In this country, through force of circumstances, but very few would be able to follow the first course. A compromise, however, may be suggested, that all details be followed closely that do not call for a trained assistant. But in following this course the fact must not be lost sight of, that only a part of the method is put into practice, and that if the results are not as good as those obtained by Brandt and some of his pupils, the fault may lie not in the method, but in the manner in which it is employed. It would be foolishly rash to assert that Brandt's method will be successful in all cases of retro-displacements with adhesions, for conditions are occasionally met with in which the uterus for the whole length of its posterior surface is, so to speak, firmly cemented to the anterior rectal wall. But these are cases in which neither Schultze's method in deep narcosis, nor a laparotomy and a direct attempt to separate the adhesions, would be of any avail. I have already referred elsewhere[1] to a case in which Professor Schultze had failed after three different attempts under deep narcosis, and in which Brandt succeeded with his treatment in six weeks.

The time consumed in the treatment of these conditions by Brandt's method naturally varies with each case and is dependent upon a number of circumstances. In the less severe cases the progress made from day to day is quite marked and encouraging, and a few weeks usually brings about the desired end. In others again, the greatest patience and perseverance on part of both physician and patient are necessary, and months may elapse before any noticeable effect is produced. My own observations have extended over too short a period to enable me to speak definitely as to the permanency of the results obtained. I am trying to follow up my cases conscientiously, and will report later to this Section on this point. I should be pleased to have the results of my treatment controlled by some members of this Section, who would examine the cases before being put under treatment, and after the treatment had been discontinued, say for a period of two months. In this way the profession would be afforded a report free from bias or prejudice, showing what the method is capable of accomplishing. Before concluding I cannot refrain from the temptation of reporting two cases out of a number that I have treated since my return from Stockholm. But I apologize at the same time for presenting them in so incomplete a form. I present them, however, merely for the purpose of showing what Brandt's method may achieve in rather unpromising pathological conditions, and not as indisputable evidence of the permanency of the results of the treatment.

Case I.—S. H——, aged thirty, married fifteen months, came to Mount Sinai Dispensary January 6th of this year,

[1] New York Medical Journal, January 24, 1891.

and gave the following account of herself: Shortly after marriage began to suffer with dyspareunia for which she consulted a doctor who introduced a pessary which gave her some relief for a time. She then became pregnant and aborted about the fifth month. This she attributed to a fright. While pregnant she had constant pain in the hypogastrium and in both groins. She stayed in bed for six days after the miscarriage, and when beginning to go about she had pain in the back, hypogastrium, and severe sharp pain in both groins. She now began to suffer again from dyspareunia, and her periods now for the first time were attended with excruciating pain. All these symptoms persisted until her visit to the dispensary. She was treated at the dispensary for a fortnight with galvanism applied to the vaginal vault and abdomen, with but little relief to her symptoms.

On January 20th, after a very careful examination, the following note was taken: Uterus retroflexed, with the fundus high up in the pelvis, and lies considerably to the right of the median line. Rather firm bands passing from the fundus to the anterior rectal wall, and from the side to the right pelvic wall. Right ovary and tube not detected. Left ovary somewhat enlarged and slightly fixed to the left pelvic wall.

Diagnosis.—Retroflexion, with firm perimetric adhesions. Left oöphoritis. After three daily applications of pelvic massage and stretching, the period set in at the natural time, and was absolutely free from pain. Two days after the cessation of the period, which was on January 28th, she called at the office and stated she had no pain anywhere. The uterus was quite movable, though it still lay in sharp retroflexion. The left ovary seemed smaller, and was freely movable. An effort made to replace the uterus was unsuccessful. On the following day on drawing down the uterus with the volsellum it was easily anteverted. This had to be repeated on the next day, and as the patient, owing to domestic duties, could not continue with the treatment, a well-fitting pessary was introduced. Three days later it was found that the posterior bar of the pessary was in front of the cervix, and was consequently removed and left out. The patient had been free from pain in the meantime. When she called a fortnight later, which was February 8th, the uterus was found in anteversion, and there had been no recurrence of the pain.

Here was a case of backward displacement with firm adhesions and attended with a train of severe symptoms which was cured, as far as we can speak of a cure at present, after seven applications of pelvic massage and systematic stretching. The patient had been treated for weeks before coming to the dispensary with as little result as that of the treatment she received there.

Case II.—L. M——, aged twenty-five, married six years, had one child five years of age. She never had a miscarriage. Began to menstruate at thirteen years, was regular from the first and had no pain. Her only labor was easy; she remained in bed eight days and apparently made a good recovery. Three years ago began to suffer from pain in the right groin. Shortly after had pain in the left groin also. She began now to have in addition severe pain in the back. Her periods grew less and were attended with some pain. The usual pelvic pains were always aggravated during menstruation. She had pain on coition, which sometimes was followed by a slight sanious discharge. Micturition was frequent and slightly painful. She was subject to headaches, her digestion was impaired, and her nervous system began to be unstable.

An examination showed a retroverted uterus with the cervix fixed immediately behind the symphysis, and the fundus low down in Douglas's cul de-sac, also fixed by firm adhesions and bands and lying considerably to the right of the median line. Right ovary corresponds in size to a large hen's egg, and the right tube much enlarged and tortuous. Left ovary somewhat smaller than the right, and fixed to the pelvic wall. Left tube apparently not larger than normal.

Diagnosis. — Retroversion with fixation. Double oöphoritis. Right salpingitis, whether catarrhal or purulent impossible to say. Daily pelvic massage and systematic stretching began February 12th. On the 18th patient declared herself entirely free from pain. On the 19th after considerable difficulty uterus was replaced, but fell back into retroversion immediately afterward. The enlarged ovaries and swollen tube have undergone decided decrease in size.

Note.—The treatment was continued daily until I took ill on February 27th, and was begun again March 11th. In the interval she had had her period, which was attended with considerable pain during the first day. The pain in the right groin had returned, but was not nearly as severe as before the treatment was begun. Daily treatment with occasional interruptions was followed, and in a few days she was again entirely free from pain. Her next menses set in March 30th, without the slightest pain or discomfort. On April 11th she became completely drenched during a severe rain-storm, and on that night she again had pain in the right groin. A couple applications of massage relieved the pain, but the right ovary, from being half the size it was at the first examination, is now just as much swollen as it was then and is quite tender. The right tube is about half the thickness it was when she first came under my care. The uterus is fairly movable and can be readily anteverted. Ever since coming under treatment she has had no recurrence of the pain in the back. I consider that a laparotomy for the removal of the right appendages is indicated, and have advised it, but the patient will not submit to an operation. The case is instructive in that it shows that with ordinary care massage and stretching may be safely employed even in the presence of very marked disease of the adnexa, and it further shows the benefit to be derived from the treatment in such extensive and firm adhesions of the uterus.

167 East Sixty-first Street.

THE DRAINAGE OF CITIES AND ITS RELATION TO PUBLIC HEALTH.

By HUBBARD W. MITCHELL, M.D.,

NEW YORK.

The subject of the drainage of cities includes in its more comprehensive sense the kindred subject of sewerage, and the no less important subject of the cleansing of streets and public ways.

All these three points—drainage, sewerage, and street-cleaning—are so important and so closely allied as to form practically but a single head in the great question of public health. The neglect of these in past ages gives us a long list of mournful experiences in the plagues, pestilences, and epidemics that have so often and so frightfully scourged mankind.

If we glance backward along the line of history we find that some of the fairest provinces of the earth have been fearfully afflicted with the ravages of disease, and often whole communities have been swept away or decimated by the invasion of epidemics that owe their existence and spread to the ignorance and disregard of sanitary laws.

Men learn the lessons of sanitary rules slowly, and this is but too often seen in the appearance of loathsome and contagious ills that every now and then stalk among us like a hated spectre.

When men aggregate in large numbers within restricted limits, a condition of things at once arises that makes imperative the observance of certain laws to regulate their well-being, and these laws cannot be disregarded without our paying a fearful penalty of sickness, suffering, and death.

This aggregation of great numbers of individuasl within restricted areas, as in cities and towns, and the maintenance of the public health of these masses of individuals in relation to drainage and sewerage, and the proper con

dition of cleanliness of its streets and public ways, present a sanitary problem at once complex and difficult.

The waste matters of the human body, and of the bodies of the various domesticated animals domiciled among us, and the large amount of garbage from our cellars and kitchens, make it very important that we should get rid of these waste matters in a way that will not affect the general health. It has always been a matter of the greatest difficulty to determine the best way of getting rid of these waste matters of the body, which pass into the sewers and thence away from the place from which they are discharged. The drainage of cities has been a problem that has enlisted the best talents of engineers and sanitarians. The system of sewerage in large cities is therefore a very important matter, and it has elicited a high degree of engineering skill to devise the best method of constructing these important outlets. No less important is the matter of getting rid of the great amount of garbage which daily accumulates in all large cities and towns. Many of the diseases which afflict the human race have been generated through the decay and putrefaction of these substances which are indiscriminately thrown into the streets and gutters; the sun pouring down upon them and the moisture of the rain has set up the process of decomposition, and this has given rise to disease-germs which enter the human body and excite into activity a multitude of loathsome and painful ills.

In reviewing the history of the world we find that in all ages where a plague or pestilence has arisen the causes of these can be traced to bad drainage and to the decay of garbage and other waste matters which are thrown into the streets. Bad drainage is one of the most fruitful sources of disease. The waste matters which are poured constantly into the sinks and cesspools not being properly carried off, and the places themselves not properly cleansed, have given rise to the process of putrefaction and to a long list of maladies. In tropical cities where the drainage has been imperfect, and in some places where no drainage has existed at all, periodical epidemics have occurred with frightful regularity and with fatal results. The great plague which visited the city of Florence, Italy, in the fourteenth century was caused by the imperfect drainage of that city—in fact drainage was almost unknown, and all of the effete matters of the city were allowed to collect in cesspools or run upon the ground, and under the hot sun gave rise to putrefying gases and disease-germs.

The epidemic of cholera which swept over a large part of Asia and Europe almost annually until recently, was the result in a great measure of imperfect drainage and a gross neglect of sanitary laws. In the superstition of those times they were attributed to visitations of Divine displeasure, and the shrine-cure and the miraculous interposition of saints and others were invoked for their relief, but in spite of these, the disease continued its ravages until a more enlightened age pointed out the cause and remedied the defect.

In the city of Rio Janeiro the yellow fever which almost annually scourged that city was found to have its origin in the imperfect drainage of the city and the gross neglect of sanitary laws relating to sinks and cesspools, and the overflow of these upon the adjacent lands was one of the great causes in the production of that dreaded disease. When finally a scientific system of sewers was constructed and the drainage of the city properly carried out, and a stop put to the practice of throwing all manner of garbage into the streets, the epidemic gradually abated.

The city of Panama underwent a similar experience.

Prior to the year 1863 the city of Acapulco in Mexico was almost annually visited by yellow fever, and so fatal were its ravages that in some years the dead were left for a time unburied. About this time I had occasion to visit that city, and my opinion was asked, with that of other American physicians, of the cause of these annual scourges. A superficial examination revealed the fact that where sewers existed at all, which were comparatively few in number, they emptied their contents into a swamp a short distance back from the city. Where no sewers existed, and this was generally the case in the town, the waste matters from the houses were poured into cesspools, which were contiguous to the wells which were used for drinking-water. These wells were frequently polluted by the contents of the cesspools percolating through the soil, and this, with the imperfect drainage and the practice of throwing garbage into the streets, was the cause of the yearly visitation of yellow fever. It was suggested by myself and others that a sewer be constructed which would carry the waste matters of the city into the Pacific Ocean, and the authorities lost no time in acting upon this suggestion. Since then yellow fever has visited Acapulco but rarely, and then only in a mild form.

The city of New Orleans was almost annually visited by yellow fever before General Butler reconstructed the levees and the drains of the city, and caused the streets to be daily flushed with a supply of pure water.

The city of Memphis affords another striking example of the effects of bad drainage. The case of Memphis is closely analogous to that of Acapulco. The sewers were badly constructed, and poured their contents into a bayou in the rear of the city. The cesspools here also were contiguous to the wells of drinking-water, and here again the contents of the cesspools percolated through the soil and poisoned the waters of the wells. To add to this, the garbage of the houses was thrown indiscriminately into the streets, and these causes acting together gave rise to yellow fever, which was so severe and so fatal in that city for many years. When modern science came in and constructed a proper system of sewers, and the drainage of the city was intelligently and properly carried out, Memphis became rid of her annual scourge.

In some of the newer cities of the West the sanitary engineers have constructed things better. In the city of Denver, which lies at a mean altitude of fifty-two hundred feet above sea level, and is, during the summer months, scorched by severe heat, the maintenance of the public health is kept up by a practice of daily flushing the streets through a system of irrigation furnished by the waters of the South Platte River. From this stream, which heads in the Rocky Mountains near by, a copious supply of water is led through nearly all the streets of the city, and the gutters are kept sweet and clean. From the same source the sewers are daily flushed, and this great sanitary measure is one reason why Denver is regarded as a health-resort. Salt Lake City is likewise preserved in a similar manner. The sewers of this city are comparatively small, but a boundless supply of pure cold water is obtained from the melting snows of the adjacent Wasatch range of mountains, and this flood is poured copiously through every street of the city, and in this way the health of the city is maintained.

In the city of New York the sewers, in a large measure, are ample and well constructed, yet many of them are in a dilapidated condition. This is the fault of the authorities who have this matter in charge. Our city should be the best drained city in the world. Its configuration is such that it can be easily drained into the two great rivers which bathe its shores. In many cases, however, the sewers are sadly out of repair, and their contents are allowed to escape into the surrounding soil, saturating it with their vile contents, and whenever the streets are opened for the purpose of repairs the foul and offensive gases escape into the air. These defects are being gradually remedied, and under the intelligent vigilance of the Board of Health the sewers are being constructed in a more thorough and more permanent manner. The subject of sewer-gas has perhaps been incorrectly stated, and its importance somewhat over estimated. It is a current belief in the public mind that the gas in the sewers is under a strong pressure, and through any leak in the sewers or waste-pipes this gas is strongly forced backward into the houses. This is not

altogether true. Experiments have been made by the Board of Health and by the authorities of Columbia College to show what amount of pressure of sewer-gas existed in the sewers, and these experiments have demonstrated the fact that this pressure is inconsiderable. Even where the mouths of the sewers have been exposed above the water-mark, and where the wind has blown with considerable force into them, this has not exerted as great an amount of pressure as one would naturally expect to find.

The system of ventilating-pipes in houses leading from the basement to the roof is of great value. No modern house is constructed without a ventilating-pipe, and these carry off the noxious vapors, and discharge them into the air at a considerable height above our roofs, practically placing the danger-line out of our reach. This system of ventilating pipes and the ventilating-shaft now constructed from closets largely obviate the danger to health which formerly existed.

Closely connected with the drainage of cities, and quite as important from a sanitary point of view, is the cleaning of the streets and public ways. In the city of New York there are about three hundred miles of streets and avenues. A considerable part of these are paved, but many are not. So vast an area of ground in a city like this is a fruitful source of disease unless it is properly and regularly cleaned, and this problem of street-cleaning properly engages our most earnest attention. When it is remembered that these three hundred miles of streets are hourly traversed by the feet of thousands of men and animals, feet that are not always in themselves clean; and when it is remembered that from these thousands of animals there is dropped a vast amount of waste matter, and this waste matter is mixed with the dust and dirt which accumulate in the street, and is ground and pulverized under the feet of these thousands of animals, and under the wheels of thousands of vehicles; and when to all this is added expectorations from thousands of throats, some reeking with tobacco, some foul with disease, such as syphilis and phthisis and many others; and when to this is added the almost tropical rains, and the almost tropical suns of our summer climate, the wonder is that disease is not more rife and more rampant than it is now. If it were not for the mean equable climate and the clear skies and the pure air in which we live this great extent of unclean streets would breed a pestilence among us. To all this can be added the exhalations which arise from the sewer manholes everywhere in the city, which discharge their noxious gases into the air under our very nostrils. When all this is considered, the problem of clean streets becomes one which interests everybody among us. This problem has been variously grasped and studied, with a view of ascertaining the best means of accomplishing its purpose. At a recent meeting of the Ladies' Health Protective Association of this city a bill was read which had been prepared at its suggestion by a Mr. J. A. Ambrose. This bill was drawn with the idea of presenting it to our Legislature at Albany, and asking that body to enact a law which should place it at once into effect. Its scope, briefly stated, was to divide the city into districts of convenient size, beginning at the Battery and ending in the Twenty-fourth Ward. These districts were to be respectively numbered from one upward and each to be placed under a foreman. Under him were to be placed a number of men and a number of sweeping-machines, with sufficient carts, horses, shovels, hoes, and brooms to keep his district in perfect order. It was suggested that the machine should go over every street under his charge once each day, and following the machine were to be a sufficient number of men with hand-brooms to sweep the matter into heaps, and these were to be taken up by carts immediately after. This was to be done each morning. During the day the men who had a specified part of the street to take care of were to sweep it with hand-brooms, and place the sweepings into small vessels or tubs mounted upon wheels. In this way all droppings were to be immediately gathered up and not allowed to remain in the street. The workingmen were to be selected for their respectability, and were required to speak the English language, to have some badge or cap to distinguish them from others, to be permanently hired by the year, and to be discharged only for cause. Their pay was to be such as would secure to the city proper talent for this work. Each district foreman was to be under the charge of a superintendent, and the whole to be under the supervision of a commissioner of street-cleaning. It was thought that if such a bill could become a law, and the process of street-cleaning carried out practically in this way, that each street would be cleaned once each day thoroughly, and the more important and more frequented streets and avenues be cleaned several times a day. Other provisions of the bill were that no garbage should be thrown into the streets, that ashes and waste-paper and all matters of that kind should be carefully collected in barrels and removed once each morning by a proper system of collection in carts. By such a system the streets and avenues of New York could be kept in a clean and healthful condition, and many diseases largely abated and held in check.

Another matter of great importance, which bears very strongly upon the problem of street-cleaning, is the maintenance of our pavements in a proper condition. If a pavement is allowed to become broken and uneven, no amount of sweeping could keep it clean. Waste matters will accumulate in these hollows and depressions, and under the influence of sun and rain and the putrefaction of organic matters contained in them, and the evils resulting from the decomposition of filth and decayed matters, disease will follow inevitably; therefore it is a matter of the highest importance that in a great city like New York the pavements should be kept in a smooth and excellent condition. In this way the streets can be cleaned with less difficulty. It is also important that gas-pipes and steam-pipes, which are laid under so many of our streets, should be constructed of such material as to prevent the leakage of these gases into the surrounding soil, thereby contaminating it. As they are constructed at the present time the leakage is considerable, and when streets are disturbed and torn up for the purpose of repairing these pipes, the soil gives out a most intolerable odor, which is not only extremely offensive but very deleterious to health. This is an evil of considerable magnitude in this city, and should receive the earnest attention of the authorities to abate it as far as possible. In considering the drainage and the sewerage of a great city like New York, it is only necessary to say that while drainage deals with the problem of removing surface-water from the streets and whatever moisture may exist in the soil emanating from springs, brooks, and swamps—and the problem of sewerage deals with the carrying off of these waters, and of the waste matters from houses and other buildings, through proper conduits, together with all excrementitious matters—the two subjects of drainage and sewerage may be practically regarded as one. The topography of a city or town has an important bearing upon its system of sewers and drains. In New York city the topography is of the most favorable character. The city is flanked on either side by a broad river with a rapid tide, and the city itself is practically a water-shed rising at the sides from sea-level and reaching a central summit of from five feet to one hundred and fifty feet. With such a configuration and natural slope of the land, there is no reason why New York should not be the best-drained and the best-sewered city in the world. An ideal system of sewerage and drainage and street-cleaning which is possible and practicable in the city of New York may be briefly stated as follows:

1st. To remove all abattoirs as far as possible from the city limits, and to provide for the proper care of the refuse of such places, and to keep them in such order that no unpleasant odors can be detected anywhere about them.

2d. The removal of cattle-pens and cattle-yards and sheds beyond the city limits, in order that the noxious and unwholesome emanations from these places may cease. Such places, even under the most favorable circumstances, usually give rise to noisome smells, which are deleterious to public health.

3d. The proper disposal of all stable refuse, and its immediate removal from the pens, cellars, and other places where it is kept.

4th. The sewers should be of sufficient size and constructed in the best possible manner of brick, lined with impervious cement, and of waterproof stone-pipe, or of iron pipes, or of all three where needed, and so laid as to have their discharging mouths pass into the rivers on either side of the city below low-water mark. Into these main sewers should pass smaller sewers, and into these again the waste-pipes from the houses and other buildings provided with properly constructed traps. In every house and building where water is used and waste matters are to be sent away the pipe connecting with the sewer should be of wrought-iron of proper size. This pipe should extend up through the entire building to the roof, and discharge its vapors at a sufficient height above the houses. Into this pipe should lead all pipes from closets, wash-bowls, sinks, and tubs, and each should be provided with a well-constructed trap. All such pipes when used for the carrying off of waste matters should be sufficiently flushed with water and kept so clean that no odors can possibly be detected in them. Where the water is abundant, as in our Croton system, enough can be used to keep clean such pipes without undue waste.

5th. All closets should be constructed with a ventilating shaft leading directly to the roof, surmounted with a properly constructed skylight with ventilating apertures.

6th. All surface-waters of the streets should be carried off by properly constructed gutters and sewer-openings, and drained and discharged directly into the sewers, and allowed in no instance to accumulate anywhere. If springs, or brooks, or swamps formerly existed in any locality, they should be properly drained, and the drainage carried to the nearest sewer.

7th. Every paved street in the city should be swept by sweeping-machines once each day and the sweepings immediately removed in carts. On streets and avenues where the traffic is great men should be stationed with hand-brooms and with small tubs on wheels, or hand-carts, and remove all droppings and refuse matter several times each day.

8th. No ashes, garbage, waste-papers, or other matters should be thrown into the streets or gutters. Ashes and garbage should be placed in suitable receptacles, preferably of metal, which every morning should be placed in the front area, where they can be emptied at an early hour into carts provided for that purpose.

9th. Pavements should be kept smooth and even, so that no sweepings or refuse matter can accumulate in holes or uneven places, and if such depressions should exist they should be swept by hand immediately after the sweeping machine passes over them.

10th. The construction of water-pipes, gas-pipes, steam-pipes, and other pipes, which are laid so extensively under our streets, should be constructed of such material, and with such excellent workmanship, that their contents should not escape into the surrounding soil, and thus contaminate it and make it unwholesome when disturbed.

With such a system of drains and sewers, and the daily sweeping of the streets, and of the daily removal of ashes and garbage and other waste matters, and the constant exercise and due care in keeping waste-pipes, sinks, and closets sweet and clean, and the ventilating of houses by fresh air uncontaminated by clouds of dust which arise from unswept streets—with such precautions as these, the health of this and other great cities can be properly maintained. Such a condition of things can only be brought about by an honest administration of a city government, and the co-operation and support of every citizen within its limits. When this is done intelligently and by all the aids known to modern sanitary science, disease will be largely abated, and the public health maintained at its proper standard. Probably there is no spot in the world so admirably adapted for a great commercial centre as the island upon which this city is built. Surrounded as it is on all sides by wide and deep channels, having a regular and well-defined water-shed, and combined with every variety of surface, blessed by a most salubrious climate, there is no reason why it should not be the most healthful residence in the world. Nevertheless it has been in times past scourged by the outbreak and spread of such dangerous and loathsome diseases as small-pox, diphtheria, and the whole class of low-grade fevers. This has been due to an improper construction of her sewers and drains, and a disregard of even ordinary cleanliness of her public streets. Science has now come to our rescue, and by her enlightened and beneficent aid, there is no reason why the city of New York should not be the most beautiful and delightful, as well as the most wholesome, place of residence in the entire expanse of this great continent, stretching as it does through the most favored climatic zones, from Maine on the north to the rich sub-tropical verdure of the Rio Grande on the south.

747 Madison Avenue, May 8, 1891.

A CASE RELATING TO THE INFLUENCE OF MATERNAL IMPRESSIONS UPON THE FŒTUS.

By R. OSGOOD MASON, M.D.,

NEW YORK.

The Record for May 18, 1889, contained a communication from me intended to show that physicians and others, who believe that strong impressions made upon the mother during pregnancy may have an influence upon the fœtus *in utero*, even to the extent of causing marked physical changes, need not necessarily be believers in *witch broth* and such like supernatural things, but may be well-informed, thoughtful, and even scientific people. While preparing that communication a newspaper item fell under my observation referring to a family of albino children in Harrisburg, Pa., presenting some interesting features bearing upon the subject in hand, and having the authority of the attending physician, Dr. M. K. Bowers, of the same city. I at once wrote to the doctor in regard to the matter; he kindly replied, and I found in him a most interested and intelligent observer and correspondent.

The following facts were elicited which, with the doctor's permission, I have prepared for publication.

Two years ago, when our correspondence commenced, the family referred to consisted of father, mother, and three albino children. The father of the children is a very dark-skinned man with black eyes and jet-black hair; the mother is not quite so dark, but has dark hair and dark blue eyes. The grandparents all have dark complexions and dark hair, and the family, as far back as its history can be traced, is entirely free from freaks or abnormalities of any kind.

Two years previous to the birth of the first albino the mother gave birth to a perfectly normal, healthy child having dark eyes and very black hair. This child died just previous to her next pregnancy.

With the second pregnancy everything went on as usual until near the beginning of the second month, when one day she unexpectedly received a small box by express from a friend in Philadelphia. She was quite ignorant of the contents of the box, which, however, was at once opened in her presence and was found to contain a large, handsome, perfect albino rat. As soon as she saw it she became nervous and declared that the sudden impression made upon her would show itself upon her child.

The rat, however, was tame, and was at once domiciled in the house. It became a general pet in the family, the pregnant woman herself also becoming very fond of it, often playing with it and holding it in her hands. A short time before her confinement the rat was accidentally killed, an incident which caused her considerable annoyance and sorrow.

A few days later the doctor was called to the confinement, which resulted in the birth of a fine boy baby, but a perfect albino. The mother, when informed of the fact, did not seem at all surprised, but said at once, "I knew it, I told you so. It was the rat—oh, that rat!" However the boy grew beautifully and became a great pet both at home and abroad, "the mother herself becoming *wonderfully* attached to him."

The mother soon became pregnant again, and informing the doctor of the fact, she remarked that she had made up her mind to have a pair of albinos. Her expectations were realized, and in due time she was delivered of a fine girl baby, also a perfect albino.

Upon the occurrence of her next pregnancy she remarked that this ought to be a black-haired baby, but she feared she would be disappointed. Her fears proved well-founded, and her pregnancy resulted in another perfect albino girl.

So, dating from the white rat episode, we have three perfect albino children, concerning whom the doctor writes: "The children are remarkable for their health, never having been sick, general activity, and unusual intelligence. They are much better specimens of the albino type than any found in museums or circus shows. They have snow-white hair, eyebrows, and lashes, the hair being remarkably fine and soft. The eyes are extremely sensitive to light, and when exposed to the sunlight or a bright artificial light they keep them closed; but in a subdued light or on a cloudy day, they are wide-awake and have very acute vision, being able to see the smallest objects, even when the room is quite dark. The sclerotic is of a dull white, a distinct bright pink (almost red) line binding its juncture with the cornea. The pupil is of a slightly darker shade of pink. The eyes are constantly in motion, never resting more than a moment upon any one object. The two older children are extremely bright and active, and the new-comer, now four days old, promises to rival her distinguished brother and sister. She is an unusually fine baby."

Such was the state of affairs in the albino family in May, two years ago.

During the second week of April last I received another letter from Dr. Bowers, from which I gather the following interesting facts. The albino children were all living and in excellent health; furthermore, on Sunday morning, April 5th, the doctor was again called to attend the mother in her confinement, when she gave birth to a perfect and vigorous twelve-pound boy, with black hair and dark-blue eyes, as utterly unlike the albinos as it was possible to imagine. The three former children are, if possible, more pronounced albinos than they were two years ago, and the family, as at present constituted, presents a most singular and interesting group.

The doctor then goes on to say: "This last dark-haired, normal child appears to be a striking example of will-power exerted by the mother. She has been under my care continually, and I know that it has been her one chief desire to have such a child. She was exceedingly anxious to become pregnant, and when she was convinced that such was the case she sent for me, and during our conversation made this remark: 'Now, doctor, keep your eye on me, for I am sure it is all right, and this time it will be a black-head!' She at once sent her albino children away to her mother's house, to remain during her pregnancy, and her husband tells me that her one constant song and desire was for the dark-haired baby. She talked of it constantly, she even talked of it in her sleep." When called to attend her she at once said to the doctor, "Now I am ready for my dark baby."

The doctor remarked that the desire on the part of his patient for a dark-haired child was not merely the whim of an ignorant or illiterate person; on the contrary, she was well educated, generally intelligent, and an unusually brilliant woman. Her parents were educated people—her father at present holding a prominent position in one of the offices of the State Government—and that her desire was accompanied by a very strong faith and intelligent effort for its fulfilment.

The case is simply one, and a strong one, bearing on the question of the possible effect of maternal impressions upon the fœtus *in utero*.

The case sums up as follows: Parents both dark—one *very* dark, to whom is born, as might naturally be expected, a dark-complexioned child.

Early in the second pregnancy of the mother she is surprised and made nervous by the sudden and unexpected appearance in her family of a large, handsome, albino rat. She affirms that it will have an effect upon her unborn child.

Albino number one is born. She becomes exceedingly fond of it; its peculiar face is ever before her. She is not averse to another similar child, but desires it.

Albino number two is born. The next pregnancy she hopes may terminate by the birth of a dark-haired child; but she is surrounded by the same influences, and the same models are before her. She fears disappointment, and she experiences it.

A third albino child is born. Upon the occurrence of her next pregnancy she is thoroughly aroused, and is influenced by a peculiarly strong wish for a dark haired child. She affirms that it will be so. She exerts her will to promote her wish. She removes from her sight the models which she does not wish should influence her. She directs her mind constantly to the ideal of a dark-haired child. She dreams of her dark-haired child and speaks of it in her sleep—an important fact as indicating unusual susceptibility to impressions. She feels that she will not be disappointed, and she is not. A perfect dark-haired child is born.

The "coincidence" man is abroad, but he has a sallow and antiquated look, and along with his friend, the "unconscious muscular action" man, seems to belong more properly to the early part of the century. Experimental psychology is bringing to light many important facts showing mind producing physical effects beyond the limit of actual nerve supply. Why not in cases like that above cited? I think we have occasion to thank Dr. Bowers for his interesting case in point.

How to Keep Needles from Rusting.—Dr. R. H. M. Dawbarn writes to the New York *Medical Journal* regarding the above subject: "For the past year I have been pleased with the results of a new plan—new to me, that is, though very probably not to others. This is simply to keep my needles in alcohol. For extreme safety against rust I use absolute alcohol; but the commercial article would probably be efficient. At least, some needles that I have kept in common alcohol for a month as an experiment are as bright as ever. Upon buying the needles I immerse them in benzine to remove grease. Then, after running them through a towel, I plunge the point (a cutting-edge Hagedorn) into a bit of cork the size of a pea—to avoid dulling from jolting—and finally, with their corks, they are put and kept in a wide-mouthed, glass-stoppered bottle filled with absolute alcohol. After use, I sew through a thick, wet, soapy towel repeatedly, cleanse the eye with a thread, immerse in benzine, and finally replace in the alcohol. This last is certainly an efficient disinfectant, besides being an excellent protector against rust. By the bye, I long ago gave up using (save in bowel work) any other than Hagedorn self threading needles, which are a decided comfort, and, when properly made, do not cut the thread."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 11, 1891.

THE DETECTION OF ABSCESS.

THE diagnosis of an abscess, especially of one near the surface is ordinarily considered so simple a matter that many text-books lay down scarcely any rules for the guidance of the surgeon. It is usually simple, yet every now and then we meet with cases in which it is of the utmost importance to know whether pus be present or no, and do what we can we cannot be sure. Even an exploratory puncture sometimes fails to give us the desired information, or rather misleads us by giving us reason to believe that pus is not present when it is. In a chapter with this heading, in his excellent "Studies from Old Case Books," Sir James Paget refers to two or three points of considerable importance in the diagnosis of this condition, which are sometimes overlooked or forgotten by the surgeon, but which, if remembered, might save him from an occasional embarrassing blunder. Among these is the condition called by the author "central softening, such as gives a feeling of softness or easy yielding to pressure in some small portion of a swelling, or of any part of which the rest is firmer or more tense than is natural." This central softening is to be detected by drawing the finger slowly and with even pressure over the suspected part, and when it reaches the point, if there be any, where pus has begun to form a slight yielding will be felt. This soft spot is sometimes of very small area, but its presence is diagnostic and is enough, in the words of the writer, "to justify puncture, incision, scraping, or any other operation that in each case may be deemed best." This sign is especially valuable in suppurating lymph-nodes, [yet there are here at least two sources of error which are to be avoided in judging of the evidence furnished by the finger. The first of these is in the case of a cluster of inflamed lymph-nodes, in which the spaces between the indurated glands may simulate the central softening. The other is in the case of acute cervical lymphadenoma in which the rapid softening of the tumor imitates abscess formation, a condition which, the author confesses, once so far deceived him as to lead him to puncture the swelling in the expectation of letting out pus. This diagnostic point is seldom mentioned in works on surgical diagnosis, and is usually learned only by practice, sometimes, we doubt not, never learned, but it is a most practical one. It is of special utility in cases of phlegmon seated near the surface yet not exactly superficial, which causes perhaps no tumefaction but only a little redness and some tenderness. Sir James Page mentions several cases of this sort which he found recorded in his note-books, in which there was apparently a superficial phlegmon. Careful search with the finger-tip revealed a spot of central softening, not raised or pouting, which, on incision, proved to be the beginning of a fistulous track, several inches in length, passing down to a deeply seated abscess. The author touches on many other interesting points in this chapter, which we are obliged to pass over, but which are well worthy of consideration and of storing in the memory for future need.

THE EXECUTIONS BY ELECTRICITY.

THE recent executions by electricity at Sing Sing are reported to have been successful, and to have fulfilled the anxious expectations of the advocates of the new law. It is with a feeling of great relief that one hears that success has this time offset the horrors enacted last year at Auburn, and that science, which heretofore has so nobly lent its best efforts to saving and prolonging life, has at last succeeded in showing its power to kill effectively, quickly, and almost pleasantly. The experience with Kemmler resulted in extra precautions regarding power and duration of currents, and, as far as the scientific witnesses are allowed to say, death in each instance was without a struggle or a mishap. It is also reported that the voltage averaged 1,600, and no chances were taken upon a single stroke. There was a grim humanity about the proceeding of repeating the shocks in quick succession, which relieved the minds and consciences of those who guaranteed the criminals against unnecessary suffering. The electrodes were well protected, and it is asserted that no burnt sacrifices resulted.

No official report has yet been issued regarding the details of the killing, and there is nothing beyond the mere results in death which have at present any scientific interest. The extra precautions taken to prevent the expression of independent personal views will necessarily detract from the value of the verdict when finally rendered. The forced secrecy of the proceedings will strike every fair-minded person with a surprise and suspicion which it will be exceedingly difficult to offset by any carefully-worded official document. It can scarcely be believed that a party of scientific gentlemen could submit to be gagged by a prison official, and be prevented from expressing any opinion regarding scientific phenomena of which they were the selected and skilled witnesses. They are thus placed in the humiliating position of a jury having a nominal power without a voice, and presumably helpless in combating foregone conclusions. But, if we must have capital punishment, what advantage have we gained by electricity over hanging? We have seen that it may fail horribly unless extraordinary precautions are taken. It has been claimed by those who appear to know that the torture of Kemmler was grossly exaggerated. We can testify to the contrary, and assert that no adjectives are strong enough to do justice to the dreadful scene. The most that we can hope is that history may never repeat itself in that direction.

Execution by electricity renders necessary a complication of machinery, the utmost skill in its adjustment, and greatest care in its management, and always entails the

employment of scientific experts—all to satisfy the mere whim of some world-betterers who believe that death is thus rendered easier and quicker than by other means. It is yet to be proven that it has any real advantage over ordinary hanging. Those who have compared the methods are willing to affirm that hanging is rarely attended with much real suffering, that the moment the noose is tightened sensation is abolished, and that death is, for all practical purposes, sure and speedy. The rope has the additional great advantage that when used in the ordinary way it seldom misses its aim, is easily worked, and within the reach of the most primitive community.

IMPROVEMENTS IN THE CORONER SYSTEM.

The recent refusal of the Comptroller to pay our county coroners their salary until they had rendered an account of their fees again calls attention to the deficiencies in our present coroner system. We feel sure that it is only a matter of time when public sentiment will be aroused on this subject sufficiently to demand a reform.

It is perfectly understood by all who have conscientiously examined the matter that our present methods are cumbersome, expensive, and inefficient. It is quite as well understood that a change is prevented largely through the fact that there is lots of "politics" in the present state of affairs.

Dr. H. O. Marcy, who has recently reviewed the existing coroner laws of the United States has reached the conclusion that the following changes and reforms are needed :

First. To abolish the office of coroner.

Second. To dispense with jury service.

Third. To separate the medical from the legal duties in all cases involving the examination into the causes of death where crime is suspected.

Fourth. To entrust the medical examination only to competent medical officers properly trained in their work.

Fifth. To make the number of these medical officers as small as consistent with the proper discharge of their duties.

Sixth. To consign all questions of law only to properly qualified legal magistrates.

Seventh. To remove the appointment of these officers entirely from the question of political consideration, and to be based only upon their possession of the requisite and proper qualifications.

Massachusetts alone has already carried out successfully most of these suggestions.

THE PAN-AMERICAN MEDICAL CONGRESS.

The project of holding a Pan-American Medical Congress at Chicago in 1893, during the World's Fair, is meeting with various criticisms, and does not yet seem to receive a very hearty response. One objection urged is that it is the year of the International Medical Congress to be held in Rome. Another objection is that while geographically and politically the New World has certain common ties, yet we are practically very widely divided by differences in race, language, and social development. While all this is true enough, it seems to us that the facts mentioned furnish a reason for making an effort to secure greater unity. The southern republics have many ancient schools where medicine is well taught and there is no doubt that the bringing together of medical men from many remote districts of the New World would be beneficial in various ways. We should probably learn a good deal regarding the racial and climatological variations of disease, and also many useful things regarding the materia medica and therapeutics of these regions. Furthermore, it will be a little change, and a somewhat refreshing one, to hear from Chili, Brazil, and Panama instead of from the German laboratories. We trust, therefore, that the Pan-American Medical Congress will be well supported by the physicians of this country.

THE MEDICO-LEGAL ASPECT OF THE JACK-THE-RIPPER CASE.

Much interest has been excited during the past week over the trial of an alleged "Jack-the-Ripper." The circumstances of the crime have been made very widely known. A woman of the lowest class was found one morning murdered and mutilated in an East Side resort. The person with whom she slept that night had disappeared, but the police apparently feeling it a matter of pride to capture some one, secured a half-witted Algerian who had slept in a room in the same house on the same night. In the course of time a very pretty web of circumstantial evidence was woven about him. The most important of these circumstances was the fact that stains of blood were found on the Algerian's clothes, on the floor or door between the rooms, and of course on the bed or clothes of the murdered woman. It was asserted by the medical experts that these stains all were mingled with matter which came from the small intestine, and that this chylous material came from a meal that was in the same stage of digestion. This identity of the different blood and fecal stains, so far as we can make out from the reports, was based on the fact that tyrosin, and perhaps other products of pancreatic digestion, were found in them all, as well as in the scrapings from the prisoner's nails. Tyrosin is a substance which crystallizes usually in the shape of fine needles grouped as radiated stars. In this respect it resembles somewhat hypoxanthin. It reacts to certain tests; but other bodies, such as sarkin, react in a similar way. Tyrosin is found in the urine in certain diseases. Altogether it would seem a little hazardous to convict a man on the microscopically established identity of minute collections of blood and intestinal matter. But the lawyers for the prosecution were skilful and the police had collected a voluminous mass of minor evidence, mostly from criminals. The result was a conviction of murder in the second degree. The medico-legal points raised were very interesting, and we do not doubt that the evidence was given most conscientiously. It is to be hoped, however, that it will be submitted some time to the judgment of the profession. At present there seems to be a feeling that the accused was made a scape-goat for the reputation of the Police Department.

The Prevention of Phthisis.—A French writer observes that the prophylaxis of tuberculosis may be summed up in five words: "Keep water in the spittoon."

News of the Week.

Medical College Commencements.—Harvard Medical School, on June 25th, graduated a class of 63; Yale Medical Department graduated a class of 15 on June 23d; Maine Medical School, on June 24th, graduated a class of 28.

Psychical Research in France.—The French have joined in the investigation of ghosts, telepathy, haunted houses, etc., and have begun the publication of a journal called *Annales des Sciences Psychiques* in which to record their work. The journal is edited by M. Dariex, who is assisted by M. Richet and other men eminent in science. We trust that their work will be fruitful.

Under the Title "Somewhat Uncanny," we published in our news column a statement to the effect that Dr. Rachel Tenny conducted a post-mortem on the body of her deceased daughter. The statement was credited to the daily papers, and was an Association despatch. Dr. Eliza Mitchell, of Kansas City, writes us that the daughter was in fact only a stepdaughter, and that Dr. Tenny did not conduct the autopsy, and was only present part of the time. We take pleasure in making the correction. Dr. Mitchell writes: "I would further add that the patient was the victim of Christian Science, having been a sufferer for two years, and during that time sought to convince herself that she was sound in body. When past hope she became convinced of her folly, and sought help, desiring to live that she might, in their own meetings, expose the fallacies which cost her her life."

The Fourteenth Italian Medical Congress will be held at Siena, August 16, 17, and 18, 1891.

State Board of Health of Kentucky.— At a recent meeting of the State Board of Health of Kentucky, held at Louisville, it was "*Resolved*, That the Secretary be instructed to place upon the list of medical colleges, the diplomas of which are to be certified to and indorsed for registration under the laws of this State, only such colleges as shall, after the session of 1891–2, exact of matriculates and graduates a minimum of requirements not lower than that required by the American Medical College Association."

The Inter-Continental American Medical Congress.— The committee appointed by the American Medical Association to effect a permanent organization of the Inter-Continental American Medical Congress, met at "The Arlington," Washington, May 7, 1891, and elected the following officers: Drs. Charles A. L. Reed, Cincinnati, O., *Chairman;* J. W. Carhart, Lampasas, Tex., *Secretary;* I. N. Love, St. Louis, Mo., *Treasurer*. On motion, the officers were appointed a special committee to draft a constitution, and report the same at the adjourned meeting of the General Committee, to be held at St. Louis, Mo., October 14, 1891, when the time and place of meeting of the Congress will be decided and permanent officers be elected.

A Curious Comment on the Accuracy of Vital Statistics.—The New York City Board of Health notified physicians that there was a neglect in reporting births. The result of the notice was an increase in births in two succeeding weeks of from 697 to 1,288.

More City Hospitals.—The Health Board have approved a recommendation to build a new reception hospital at East 138th Street and to enlarge the Willard Parker Hospital and the East Sixteenth Street reception hospital.

The American Society of Microscopists will hold its fourteenth annual meeting at Washington, D. C., August 10 to 14, 1891.

A Five Years' Medical Course Required in Canada.— The Medical Council of the College of Physicians and Surgeons of Ontario recently passed the following resolution: "On and after July 1, 1892, every student must spend a period of five years in actual professional studies, except as hereinafter provided, and the prescribed period of studies shall include four winter sessions of six months each and one summer session of ten weeks; the fifth year shall be devoted to clinical work, six months of which may be spent with a registered practitioner in Ontario and six months at one or more public hospitals, dispensaries, or laboratories, Canadian, British, or foreign, attended after being registered as a medical student in the register of the College of Physicians and Surgeons of Ontario; but any change in the curriculum of studies fixed by the Council shall not come into effect until one year after such change is made."

The Trouble at the German Hospital.—The medical board of this hospital announce that: After a careful investigation into the difficulties between the superintendent of the German Hospital and the gentlemen composing the house staff, which difficulties resulted in the discharge of the superintendent and the resignation of the entire house staff, the medical board of the German Hospital does hereby declare that

1. Such sudden resignation of the entire staff was justified by the extreme and continued provocation on the part of the superintendent.

2. That the members of the house staff, at the request of the medical board, willingly continued to discharge their duties until relieved by the appointment of their successors.

3. The members of the house staff—viz., Dr. Fred. E. Sondern, Dr. Alfons Müller, Dr. Henry A. Kurth, Dr. William Ch. Gueth, Dr. Edw. Staehlin, and Dr. Ernest C. Schultze— have at all times during their term of service attended to their professional duties to the entire satisfaction of the visiting physicians and of the medical board.

[Signed.] Hermann G. Klotz, M.D.,
Ernst Schottky, M.D.,
Augustus Caillé, M.D.,
Medical Board.

Dr. Charles H. Shears who died June 9th, at Sharon, Conn., was born in Washington, Dutchess County, N. Y., and had practised in Amenia, N. Y., and Sharon, Conn., since 1859. He studied medicine in the New York Medical College and in the Medical Department of the University of Vermont. His consulting practice was large, and he enjoyed in a marked degree the confidence and respect of his professional brethren. He was especially well known for his kindness to the poor, and there were many affecting scenes at his funeral.

A Law for the Prevention of Syphilis.—The Massachusetts Legislature has enacted a law which provides that all inmates of charitable or penal institutions who are found to be suffering from syphilis shall be isolated and treated, and if necessary detained in the institution until the infectious stage of their disorder is passed.

The New York College of Dentistry will open in the fall in a new and commodious building on Twenty-third Street, just east of the College of Pharmacy. The upper story of the Demilt Dispensary, which the College has just vacated, has been rented to the city for the use of one of the civil courts.

Dr. Sara C. Seward, a medical missionary in India, died recently of cholera at the Presbyterian Mission Station at Allahabad. She was a niece of William H. Seward, and was one of the first medical missionaries to go to India. She studied medicine in this country, and soon after receiving her degree accepted the appointment of medical missionary to India in the Zenana Mission, then just organized to send female physicians to treat and teach the women of India.

A Literary Course for Students of Medicine.—The Secretary of the Illinois State Board of Health, Dr. John H. Rauch, has issued the following circular, dated June 6, 1891: "There is a demand, from medical teachers and young men that intend to study medicine, for a literary course preparatory to the study of medicine. This demand has been met by a few of the literary institutions in the United States, and it is hoped and believed that it will be much more generally met during the next two years. The following institutions now offer science courses for students that intend to study medicine, or that intend to teach or otherwise engage in biological work: 1, University of Wisconsin; 2, University of Pennsylvania; 3, Johns Hopkins University; 4, University of Notre Dame; 5, Yale University; 6, Cornell University; 7, Princeton University; 8, Lake Forest University; 9, Northwestern University; 10, West Virginia University; 11, University of Kansas.

"As must be obvious, such a course should be based on biology, and should include thorough work in this science, as well as in osteology, comparative anatomy, and chemistry, with English, French, German, some Latin, clay modelling, free-hand drawing, mineralogy, mathematics through trigonometry, physics, mechanics, logic, general and pharmaceutical botany, and (in the last year) psychology. It is of course understood that botany, being a branch of biology, should have a prominent place in the course. The catalogues of the universities mentioned contain the lists of studies offered in their science courses. Such a course should extend over four years. This will involve no loss or waste of time to the student. The Illinois State Board of Health now requires that students of medicine matriculating in the autumn of 1891, or thereafter, must study medicine four years, and must attend three courses of lectures, no two in the same twelvemonth, in order to obtain a license to practise in Illinois. This rule will apply also in some other States. The Illinois State Board will, however, recognize a thorough course in science, such as indicated above, as equivalent to two years' study and one course of lectures, thus enabling the student to enter the second class in the medical college. This makes the full time of study six years in the literary and medical schools, or two years less than is required of the student pursuing a strictly classical course. Not only will time be thus saved, but the science student will be much better prepared to enter the second course of the medical school than will the classical student to enter the first year. The Illinois State Board wishes to make up a science course that can be recommended to any college wishing to adopt such a course, and, having but little time to study the subject, I desire to enlist your aid and have your advice in the matter so as to make the course as practical and as beneficial as possible. Will your faculty, therefore, make out such a course as it thinks best for the purpose, and send it to the Secretary of the Board? The demand from medical teachers and from students of medicine having been met by some universities, must be met by all that would continue to hold a high rank as educators of young men for the work of life."

The "Mattei" Cure for Cancer.—In the *Review of Reviews*, Mr. Stead has taken up the cudgels for Count Mattei, the "Italian nobleman," who advertises all over the world cures for cancer. Unfortunately, the medical journals, with one exception, think it beneath their dignity to attempt to interfere in the matter, in spite of the immense harm that must result to the public at large. With his usual energy Mr. Stead has started a test ward of five beds at a small hospital in London. He has a small committee of supervision, consisting of Sir Morell Mackenzie, Mr. Lawson Tait, and a Dr. Potter, s ıb editor of a nursing journal.—*Medical Reporter.*

The Wealthiest Insane Asylum in this country is probably the Sheppard Asylum of Baltimore. Endowed in 1857 with $560,000, the trustees, using the interest alone, have spent $880,000 in buildings and land, and still have a capital of $600,000. Dr. Edward M. Brush has just been appointed superintendent.

A Novelist's Anatomical Knowledge.—The critics are advising that brilliant cometary novelist, Rudyard Kipling, to be a little more careful about his anatomical facts before writing his next story. One of his heroes is reported as being permanently blinded by a sabre cut on the forehead, which *injured the optic nerve.*—*Medical News.* Our esteemed contemporary is too severe. Mr. K's hero develops an optic atrophy subsequent to a blow on the head and a good deal of vinous excess, which is good enough pathology for a novelist.

The French Association for the Advancement o Science will hold its annual congress at Marseilles, September 17th and 24th. One of the subjects discussed will be the sanitation of factories of chemical products.

The Fiske Prize.—The Trustees of the Fiske Fund have awarded a prize of $300 to Dr. Robert W. Lovett, of Boston, for an essay on "The Etiology, Pathology and Treatment of Diseases of the Hip-joint."

Statue to a Living Surgeon.—On May 30th Professor Deroubaix, the eminent Belgian surgeon, was presented with his statue in bronze by his colleagues of the Faculty of Medicine of the University of Brussels on the occasion of the fiftieth anniversary of his appointment to the Chair of Surgery in that seat of learning.

Dr. William M. Anderson, a native of Glasgow forty-five years of age, surgeon on the steamship Siberian, running between this port and Glasgow, died of heart disease on July 1st, and was buried at sea. He had been in failing health for several years, and had become surgeon of the Siberian, believing that a life at sea would lengthen his days.

The Biochemic School of Medicine.—A new medical sect has arisen in the West, and has already founded a college in the State of Washington, in which medicine is taught according to the biochemic doctrine, which is thus described by one of the lecturers at a recent meeting: "The innumerable cells of the human body are supplied by twelve mineral salts in the blood, which, when their proper proportion is interfered with in any manner, cause diseases of different natures, according to which mineral salt is deficient or in excess of its natural ratio; that is, the disturbance of this ratio puts the human system into a proper condition to absorb the disease germs that are constantly floating in the air. By providing twelve specific medicines by which the proper proportion of mineral salts is restored, health is regained and disease driven out by furnishing direct to the blood the same molecules that a perfect digestion and assimilation would furnish. The doses administered supply to the tissue cells the special salt, the lack of which is the cause of all diseases. Under the advance of biochemistry it has become possible to apply to each kind of tissue its own definite and peculiar salt, according to the requirements in disease. By the distinctive systems our physicians are guided in the choice of the particular cell-salts required, the immense variety and numerous complications of morbid states offering vast scope for exact medical practice wherewith to build up the great pyramid of scientific medicine of this advanced era."—*Boston Medical and Surgical Journal.*

Gynecology in Spain.—On February 23d of the present year, the Spanish Gynecological Society appointed a committee, consisting of Drs. G. Alarcon, E. Gutiérrez, A. Cospedal, and F. de Cortejarena, to consider the advisability of establishing a gynecological institute in Madrid. This committee has now reported that the creation of such an institution is urgently needed, not only in the capital, but in each of the provinces, as at present next to no provision is made in Spain for the treatment of women suffering from diseases peculiar to their sex. In the Madrid hospitals there are only a very few beds for such cases, and elsewhere things are even worse.

Death of Professor Scanzoni. — Dr. Friedrich W. Scanzoni von Lichtenfels, Privy Councillor of the Kingdom of Bavaria, and Emeritus Professor in the University of Würzburg, died on June 12th at Schloss Zinneberg, Upper Bavaria, after an illness which had lasted many years. He was seventy years of age.

The German Gynecological Society.—The German Gynecological Society held its Fourth General Congress at Bonn, from May 21st to 23d, under the presidency of Professor Gustav Veit. The meeting was opened by the President with an address on "Menstruation, Ovulation, and Conception." An interesting paper was read by Professor Dohrn, of Königsberg, on "Obstetric Practice among Private Patients." He said that though the introduction of antiseptics into midwifery practice had had good results, the full measure of benefit that might have been expected therefrom had not been attained. While the mortality of childbed had shown a notable decrease in certain large districts of Germany, in others no such diminution had taken place. The statistics for Prussia from 1816 to 1886 showed a marked decrease in the death-rates among mothers, commencing in 1870. On the other hand, those for the Grand Duchy of Baden, between 1873 and 1887, showed no marked improvement in recent years, and those for the kingdom of Saxony showed an actual increase of mortality among puerperæ in the last two years. This state of things Professor Dohrn attributed to the great increase in instrumental deliveries which greater facilities of communication and growing confidence in antiseptics had brought about in the last fifteen years. Operative interference was, according to him, to be deprecated, unless in a small minority of cases where it was absolutely necessary, and he appealed to medical practitioners to be less ready than they were at present (in Germany) in using the forceps in season and out of season. A further measure of great importance for the lowering of the puerperal death rate was the betterment of midwives, in whose hands was the entire management of ninety-five per cent. of all confinements in Germany. "The interests of the lying-in woman," Professor Dohrn thinks, "are in the majority of cases best served if she is left in the hands of an intelligent midwife who takes her instructions from a medical man." Papers were also read by Dr. Ahlfeld, of Marburg, on the "Difference in the Death and Sickness Rates of Lying-in Women in Special Institutions and in their own Homes;" by Hofmeier, of Würzburg, and Leopold, of Dresden, on the "Diagnosis of Carcinoma of the Body of the Uterus;" by Bumm, of Würzburg, on "Puerperal Endometritis," etc. The programme included forty-two papers and thirteen demonstrations. Breslau was selected as the place for the Congress of 1893, when Professor Fritsch will preside.

A Wiesbaden Physician cured a wealthy patient of a dangerous disease. He thereupon gave $500,000 to found a hospital. He should have given a like sum to his doctor.

Lack of Appropriations in Connecticut.—Among the institutions for which no appropriation for the next year was made by the recent Legislature are the hospitals at New Haven, Hartford, and Bridgeport, temporary houses for neglected and abandoned children, and the collection and publication of vital statistics.

Medicine in Japan.—Among the questions the profession in Japan is asked by Mr. Ernest Hart to decide are these, viz., the etiology and communicability of leprosy; the pathology and prevention of beri-beri; the influence of prolonged lactation upon the mother's health, upon infant mortality, and the rate of increase of population; the comparative immunity of the Japanese from scarlet fever, and the rarity of its spread; the nature of senile (?) gangrene so commonly found in middle age in Japan; the influence of the customary hot baths, particularly in infantile pneumonia; the apparent unimportance of hemorrhages in typhoid fever; and the real place of massage as a therapeutic measure.

Society Reports.

OHIO STATE MEDICAL SOCIETY.

Forty-second Annual Session, held at Sandusky, June 17, 18, and 19, 1891.

W. J. Conklin, M.D., of Dayton, President.

G. A. Collamore, M.D., of Toledo, Secretary.

A rather larger attendance was present as compared with last year. The social features of the meeting included an excursion to Cedar Point, where a dinner, concert, and the President's address awaited them. An excursion to Lakeside, Kelley's Island, and Put-in-Bay Island was also given.

The officers chosen for the ensuing year were: *President*, Dr. G. A. Collamore, of Toledo; *First Vice-President*, Dr. X. C. Scott, of Cleveland; *Second Vice-President*, Dr. A. J. Gawne, of Sandusky; *Third Vice-President*, Dr. A. R. Baker, of Cleveland; *Fourth Vice-President*, Dr. F. D. Bain, of Kenton; *Secretary*, Dr. C. A. L. Fitzpatrick, of Cincinnati; *Assistant Secretary*, Dr. August Rhu, of Marion; *Treasurer and Librarian*, Dr. T. W. Jones, of Columbus. The following members of committees were appointed for five years: Finance, Dr. H. J. Herrick, of Cleveland; Legislation, Dr. D. J. Snyder, of Columbus; Ethics, Dr. S. S. Thorne, of Toledo; Publication, Dr. E. S. McKee, of Cincinnati; Admissions, Dr. A. F. House, of Cleveland.

A telegram of sympathy was sent Mrs. Dr. A. W. Ridenour, of Massillon, whose husband, an honored member of the society, and whose name was on the programme, lay dangerously ill.

Cincinnati was chosen as the place of the next meeting, and the date as the first Tuesday in May, 1892.

The matter of contract railroad surgeons was brought up, referred from the American Medical Association, and referred to a committee of five. The resolution making the members of auxiliary societies, that is, county and district societies, members of the State society, as Indiana and other States have done, very much improving their membership, was, after some discussion, passed. The business of the society is to be done by the delegates, and all members who are now members are not to be affected by this change, *i.e.*, deprived of the right of suffrage.

The committee to get a law passed by the Legislature for the protection of physicians, reported that, not liking the complexion of the present Legislature, they had not accomplished anything.

The President's address was on Molière and the doctors, and consisted of matter mostly historical, enumerating numerous sayings of Molière concerning the doctors.

The Surgical Treatment of Chronic Catarrhal Appendicitis was ably discussed by Dr. R. Harvey Reed, of Mansfield. He discussed the uses of the appendix and concluded "everything can something do, but, pray, for what use are you?" He then paid special attention to the diagnosis. The paper was discussed by Drs. Reed, Scott, Kinsman, Ricketts, Hall, Baldwin, and Jones.

What Cases Shall be Drained After Abdominal Section was the subject of a paper by Dr. R. B. Hall, of Cincinnati. The doctor had found considerable difference in opinions and in practice. So far as he was aware he was the only one who uses universal drainage, which he does now in every one of his cases. He will continue to give his patients the benefit of the doubt by continuing to drain in every case in which the peritoneal cavity has been opened. He favors the small Price tube.

Dr. Edwin Ricketts, of Cincinnati, corroborated Dr. Hall in the use of the drainage tube in every case, though sometimes he only uses it two hours. He uses Keith's tube. Dr. R. H. Reed spoke favoring the tube. The paper was further discussed by Dr. S. S. Thorne, of Toledo, and the discussion closed by Dr. Hall, who showed samples of tubes.

Three cases of the "Radical Cure of Hernia" were reported by Dr. F. C. Larimore, of Mt. Vernon. He had operated after Marcy's method. He showed the kangaroo suture. He believed the radical cure of strangulated hernia was justly considered one of the triumphs of surgery.

Dr. J. C. Reeve, of Dayton, read a paper before the Ohio State Medical Society upon the A. C. E. mixture. He found justification in further study of anæsthetics in the wide difference of opinion as to which is the best agent, and in the fact of accidents with both chloroform and ether. The origin of the A. C. E. was with Dr. Hailey, of London, and it was strongly recommended by the Chloroform Committee of the Royal Medico-Chirurgical Society of London in 1864. Since that year the author of the paper had used it with all sorts of patients, in all kinds of operations, almost exclusively as an anæsthetic, except in obstetrics and for young children. Was the alcohol of the mixture of any value? This is answered decidedly in the affirmative upon chemical grounds: the union is a chemical combination, not a simple mixture. This annulled one of the most frequent objections to the mixture, viz.: the different rate of evaporation of the ingredients. Other objections were considered and special attention given to the physiological experiments of Dr. A. B. Watson, which showed results adverse to the mixture. Accidents from the A. C. E. mixture were studied, there had been three deaths and a number of cases in which dangerous symptoms were manifested. Of the latter, the author had met with three in his own practice, covering a period of twenty-six years. But the mixture was not presented as an absolutely safe anæsthetic, for such a thing does not exist. Finally, with a due appreciation of the insignificance of the value of any individual experience with anæsthetics, the author expresses his strong conviction of the advantages of the mixture as compared with either of the leading anæsthetics, its greater promptness, its lesser unpleasantness, and its greater safety as against chloroform.

Dr. W. G. Scott, of Cleveland, queried if persons affected with kidney trouble did not do badly under ether.

Dr. McCurdy, of Youngstown, had used all the anæsthetic mixtures and had no accident. He likes to use the A. C. E., and has had more nearly fatal accidents from ether than anything else.

Dr. R. Harvey Reed, of Mansfield, is afraid of chloroform every time he gives it, though he likes its action in other respects. He related his experiments on the lower animals and discussed the various methods of administration.

Dr. H. J. Herrick, of Cleveland, said we have many varied conditions which all demand consideration—the patient and his condition, the mixture, and the method of administration.

Dr. X. C. Scott, of Cleveland, said that we have in A. C. E. two gases, one heavy and one light. We have no assurance of how much of each our patient is getting. I have abandoned all anæsthetics except chloroform. I always give whiskey some time before giving the anæsthetic.

Dr. F. C. Larimore, of Mt. Vernon, believes in straight ether and straight chloroform. Children under ten years of age chloroform, over ten years of age ether. It is very important to have the confidence of the patient.

Dr. S. S. Thorne, of Toledo: As for me and my house, we will use the A. C. E. I never saw an evil effect from its use.

Dr. J. H. Baldwin, of Columbus, reported a death from chloroform which occurred after the cessation of the administration—four minutes. The patient (female) was inverted, artificial respiration was used, and the heart was stimulated by pricking it with a hypodermic needle. He has used chloroform in most cases, but shall not use it as confidently as before. I have used the A. C. E. and shall

use it in the future. I do not think children possess that immunity from chloroform generally believed.

Dr. T. A. Reamy, of Cincinnati, was surprised that gentlemen would use a mixture of anæsthetics and run the risk of both. I gave chloroform for years in a large number of cases and never had a death. I never saw a death from chloroform, ether, or A. C. E. I would give ether, unless there is some trouble with the bronchial mucous membrane or other mucous membrane. I can put the patient profoundly under the influence of ether in four minutes. Why not give chloroform? It is not as safe as ether. That is all there is of it. Alcohol has the same effect as chloroform. I have found the effect of digitalis on the heart magical.

Dr. J. C. Reeve, of Dayton, warned the gentlemen against the use of vitalized air, which had been brought into the discussion. It is nothing but chloroform diluted with air and perfumed. I have made careful clinical studies of every case which proved fatal since the use of anæsthetics. That children are safe against chloroform is a delusion and a snare. I do not believe that A. C. E. evaporates differently. Ether first, then the chloroform. We want further investigations. I have no faith in the action of digitalis in heart-failure from chloroform; it is all right in theory, but you cannot get its action in time.

Carcinoma a Form of Perverted Nutrition was the subject of a paper by Dr. H. J. Herrick, of Cleveland. He thought that in our ideas of cancer we were in error and that we have not made progress since the days of Hippocrates. He considered the new growth to exist in the white blood-corpuscles. The great mistake we make is to treat only the visible disease and not the constitution.

A Case of Dropsical Distention of Douglas's Cul-de-Sac was reported by Dr. J. F. Baldwin, of Columbus. The distention was very great, producing a tumor that projected at the vulva as large as a cocoanut. It had existed for two years, and was a source of great annoyance and distress. On lying down, or on pressure, the contents, which consisted wholly of serum, would pass into the abdominal cavity, and the tumor would disappear. A tumor as large as an orange existed on each side of the womb, and it was supposed that the dropsical effusion was due to the pressure of these tumors on the veins of the broad ligaments. As the patient would not consent to the removal of these growths, a less radical operation was decided upon. An incision was made through the vaginal wall into the cavity of the sac, the contents allowed to escape, and the pelvic cavity explored by passing the finger through this incision. It was then ascertained that one of the tumors was a cyst of the broad ligament, and the other a cyst of the ovary, with such adhesions that the opening between the general peritoneal cavity and Douglas's sac would barely admit the passage of the examining finger. It was decided to attempt to secure obliteration of the sac, and its inner surface was accordingly wiped over with a 1 to 1,000 solution of corrosive sublimate. A local peritonitis ensued, as was expected, and the result was a complete cure. So far as the operator could ascertain the case was a unique one, and none of the members present could throw any light upon it.

Tests for Albumin was the title of a paper read by Dr. William B. Davis, of Cincinnati. He said: Among the equipments required of the physician of to-day is that of making a thorough examination of the urine. In the United States albuminuria has been found to prevail in from ten to twenty per cent. of all persons examined; in Great Britain and Europe larger percentages have been found. Professor Grainger Stewart having demonstrated its presence in nearly one third of the population. Professor Senator, of Berlin, states in his recent work, that forty-one out of every one hundred healthy individuals, particularly soldiers, have albuminuria.

Of late years there has been a great multiplication of tests for the discovery of albumin in the urine. Posner's test, as published by Senator in his late work, is this: "Add to the filtered urine three times its volume of alcohol or a concentrated aqueous solution of tannin, wash out the precipitate with water, and then dissolve with acetic acid. Or add a large quantity of acetic acid to the urine, and then evaporate in order to concentrate the urine. In both cases in the acetic-acid solution, all the tests for albumin which are not influenced by the acetic acid will give a positive result." There is no doubt that some of the tests recently introduced are useless, others misleading, and some are very difficult of application. In order that there may be uniformity in our investigations, there should be an agreement by chemists and the medical officers of life assurance companies upon certain tests for albumin in the urine which shall be recognized as standard.

Dr. Davis here quoted a number of authorities who gave different tests for albumin, and from all the testimony he concluded that the familiar tests of heat and nitric acid were the most popular, the best, and most reliable reagents for the detection of albumin in the urine. Professor Vaughn, of the University of Michigan, wrote him that he thought the only tests which distinguished the albumins from the albuminoses and peptones were the nitric-acid and heat tests, the nitric-acid contact test, and acetic-acid and potassium-ferrocyanide test.

The author concludes, however, that the refinement of our chemical tests, and the fact that some of them give reactions with other proteids than serum-albumin, do not account for the wide discrepancy between the American and Continental reports of the prevalence of albuminuria in persons otherwise healthy.

Notes on the Treatment of Syphilis: Its Evolution and Present Status, by William Thomas Corlett, of Cleveland, O. The author went into the history of syphilis and its treatment from the time of Moses through the centuries to the present day. He finds that mercury in some form has had more ardent advocates than any other treatment. It is the only known drug which possesses any curative influence on the disease. The virus may be eliminated by the natural eliminative forces of the body in from one to thirty years, but under the use of mercury its manifestations become infrequent and finally the organism becomes free from the morbific influence. Authorities differ as to when it is best to begin the use of mercury, but doubtless the best course is to begin as soon as the diagnosis of syphilis is made. The special form of mercury depends upon the individual case, but generally speaking the protosalts are preferred to the bisalts at the beginning, as calomel, mercury with chalk, the blue pill, either alone or combined with iron. A fertile source of error is the substituting the iodine compounds for mercury. Good results will follow the mixed treatment of iodine and the prosalts of mercury late in the course of the disease. Iodine should be discontinued as soon as practicable, although mercury should be given at intervals for one or two years after all manifestations have disappeared.

The author has encountered three cases in young robust subjects over which mercury had no specific influence. The disease finally yielded to one twentieth grain doses of the chloride of gold and sodium, taken from four to six times daily. As aids to the treatment, the use of tobacco should be avoided, and a special course of living best suited to regulate his physical welfare should govern the patient. The Hot Springs of Arkansas are much frequented by those who think to have the disease "boiled out" of them, but it is quite generally recognized by syphilographers that the waters have no specific effect on syphilis, and in some instances the best physicians there have advised against their use.

Some Facts Every Practitioner Should Know About Squint.—Dr. A. R. Baker, of Cleveland, read a paper on this subject: "Is the Ambylopia of the Squinting Eye the Cause or the Effect of the Squint?" The weight of opinion seems to be that the theory of Donders is correct. A fact that every practitioner should know is that most

cases can be cured without an operation by the use of most carefully-fitted spectacles. As a general rule, the nearer the correction of the error of refraction is attained the better. In order to do this accurately the accommodation should be paralyzed with atropia in every case. Spectacles should always be given in preference to nose glasses. Treatment based upon the facts that the squint is due to the error of refraction, that binocular vision can be restored, and that squint can be cured without an operation has met with the most gratifying results. In treating cases of squint the author has usually been governed by the following rules: 1. If the squint is alternating and the vision fairly equal in both eyes it is seldom necessary to operate. 2. If the squint is fixed in one eye, but the vision of that eye good, the same rule should be instilled into the working eye occasionally, and possibly a patch kept over it, and orthopedic exercises indulged in as described by Landolt 3. If the squint is fixed in one eye and the sight very defective, and no improvement after patient trial with lenses and covering good eye, only a cosmetic result can be attained. The operation should be performed any time after the sixth year.

Abdominal Tumors.— Three cases showing unusual difficulty of diagnosing abdominal tumors were reported by Dr. T. A. Reamy, of Cincinnati. The cases were of very great interest, and were selected from a large number on which the doctor had recently operated, which showed the great difficulty of accurately diagnosing abdominal tumors. He thought an injustice was frequently done doctors who were previously in charge of cases operated on, the operator not finding the conditions present said to exist by the former physician in charge. These conditions are not always easy to determine accurately, and then, too, they sometimes change with changing years.

The Operative Treatment of Uterine Cancer was the subject of a paper by Dr. D. Todd Gilliam, of Columbus. He considered the two operations, total extirpation and high amputation, favoring the latter.

Salpingitis, with Report of Two Cases, was the title of a paper by Dr. A. B. Walker, of Canton. Operations were strictly aseptic, and no chemicals were used in the abdomen. He believes that the early treatment of endometritis would in many cases prevent the formation of salpingitis. Gonorrhœa in women becomes a matter of considerable importance in view of its sequences.

Dr. Edwin Rickets discussed the paper.

Papers were read by Dr. C. W. Tangeman, of Cincinnati, on "Convergent Squint and Its Treatment;" by Dr. A. C. Thrasher, of Cincinnati, on "Papilloma of the Larynx, with Case;" by Dr. C. N. Smith, of Toledo, "Gonorrhœa in Women;" by Dr. A. B. Richardson, of Cincinnati, "Home *vs.* Hospital Treatment of the Insane," "Influenza;" by D. N. Kinsman, of Columbus, "Convergent Squint and Its Cure;" by Dr. C. W. Tangeman, of Cincinnati, "The Value of Drainage in Cases of Bleeding After Laparotomy;" by Dr. M. Stamm, of Fremont, "Compound Gangla Treatment by Operation;" by Dr. C. S. Hamilton, of Columbus, "Hernia;" by Dudley P. Allen, of Cleveland, and others.

The University of Pennsylvania.—It is announced that important additions were made to the faculty by the board of trustees at their last meeting. Dr. George A. Piersol was chosen Professor of Anatomy, to succeed the late Professor Leidy; Dr. Harrison Allen, Professor of Comparative Anatomy, to succeed to Dr. Leidy's chair in the Biological School, and Dr. John B. Deaver Assistant Professor of Applied Anatomy. Dr. Edward Martin was elected to the chair of Special Surgery. In the Veterinary Department Dr. S. S. J. Harger was elected Professor of Veterinary Anatomy, and Dr. Leonard Pearson, who is now pursuing special studies at the Royal Veterinary School of Berlin, Assistant Professor of Veterinary Medicine.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 3, 1891.

George L. Peabody, M.D., President, in the Chair.

Tubercular Synovitis.—Dr. R. F. Weir presented a young woman who had suffered for some time with ganglions or hydrops of the sheath of the ring-finger below the annular ligament only. Numerous melon-seed bodies could also be felt very distinctly within the sheath. Recent observation had shown these cases to be tubercular. The older operation of making an incision above and below the annular ligament when the swelling existed on both sides, washing out, and making pressure, succeeded very seldom indeed, and had been abandoned for the newer one of dissecting out the sheath after first expelling the blood by Esmarch's bandage. In the present case the rubber bandage was applied, the sheath was exposed and carefully dissected out throughout its whole circumference and from the distal phalanx up into the palm. There was a moderate amount of fungous attachment up the tendon, which was scraped off. The operation was performed in February, and the patient had regained very good use of the hand, although there was yet some sensitiveness on passive motion. He said it was now claimed that tubercle bacilli could be found in all these cases.

Dr. Gibney said he had recently had a case involving one of the foot tendons, but Dr. Thatcher was unable, after examining a large number of the rice-like bodies which had been removed, to find any tubercle bacilli. In this case the operation was followed by excellent functional result.

The Treatment of Graves's Disease.—Dr. William H. Draper, in lieu of a paper promised on this subject, made the following remarks:

I chose the subject of the treatment of Graves's disease, not because I have anything to say upon this subject which would enlighten the members, but because it is a disease which has always interested me, and because the treatment of it is so unsatisfactory that I think it is desirable it should be made a subject of frequent discussion, and that the views of gentlemen who are in the habit of seeing it should be given.

Another reason why I was moved to suggest this subject for discussion is, that I think the disease is a much more common one than is generally supposed by those who regard it as consisting only in the manifestation of the characteristic triad of symptoms which first excited the observation of Graves and afterward of Basedow. I am persuaded from my own experience, as I have no doubt other members of this society must have been persuaded by their experience, that the disease often presents itself in partial, and, so to speak, rudimentary forms. The characteristic cases, those in which exophthalmus, the thyroid enlargement, and the extreme frequency of the heart's action occur, are perhaps not very common. But the partial cases, those in which one or two of these characteristic phenomena may be present, and above all in which the other nervous symptoms of the disease are present, I think are very frequent. Of course it will be admitted by all of us that the disease must be regarded as a pure neurosis. I say this not without a knowledge, of course, of the views of those who have supposed that it had an anatomical lesion. I think that the literature of the disease shows that the anatomical lesion, the lesion of the ganglia of the cervical sympathetic, is by no means a common one. Some cases have been observed in which the ganglia of the sympathetic of the neck have shown sclerotic changes. But even if this lesion could be regarded as the characteristic lesion of the disease, it is not one which would explain the phenomena. An irritation of the cervical sympathetic would account, of course, for the rapid heart action, but it would not account for the exophthalmus, nor for the thyroid enlargement. It might account, possibly, for a good many of the nervous symp-

toms which corollate themselves with the characteristic manifestations of the disease.

In my experience these nervous phenomena are, perhaps, quite as interesting as the characteristic exophthalmus, enlargement of the thyroid, and action of the heart. They manifest themselves, as you all know, by affections of the higher centres, and by very marked spinal symptoms. I have been struck in my experience with the psychical peculiarities of patients with this disease. It is well known that in insane asylums these cases not infrequently are found; I think the psychical condition most common is a melancholia, more or less well-marked. I have seen a number of cases of that sort, and I have seen it presenting the phenomena of a psychical mania. That is to say, a depression alternating with periods of considerable excitement. These patients, as we know, are extremely irritable, extremely emotional, extremely unhappy, and often show very marked symptoms of melancholia.

The other nervous symptoms which are almost always present in more or less marked degree are of spinal origin. Those which have presented themselves in my experience are great muscular tremor, sometimes very marked, sometimes only confined to the hands, sometimes quite general, and accompanied by fibrillary contractions of the muscles of the face. There has been also in some cases which I have seen a marked degree of muscular paresis, so that the patients were very feeble. I remember one lady who was under my care, and who by the way made a most excellent recovery in a shorter time than I had ever before seen the disease recovered from, used to fall in the street, and was so feeble that she rarely went out through fear she should fall down. The tremors, I think, are very common. The paretic symptoms are not always so marked as in the case I have mentioned. They are also sometimes associated with choreic movements. There are also signs of trophic disturbance, which manifest themselves in local congestions and in sweatings. I have never seen a case of unilateral sweating, which is said sometimes to occur, but I have seen a tendency to marked flushing and general sweating, and sweating of the hands and feet.

All of these symptoms, it seems to me, point to the conclusion that the disease is a general neurosis, and one which is not accounted for by either of the characteristic symptoms, for they, like these other nervous symptoms which I have mentioned, must be regarded as the result of some obscure cause about which we know nothing. The circumstances under which the disease occurs also point, I think, to the conclusion that it is a general neurosis. It has been observed that it is in a very considerable number of cases a hereditary disease, and that it is one of the transformations that are observed in persons of neurotic inheritance, occurring in families in which insanity, epilepsy, and other neurotic affections have been observed. My own experience does not show any very marked confirmation of this statement, but I think it is one which has been made and with a good deal of confidence.

Taking this view of the nature of Graves's disease, the treatment, of course, must be very variable and very comprehensive. A treatment which is designed mainly to control the action of the heart, which is perhaps the most uniform symptom present, does not cure the disease. Nor does any measure which is devoted especially to the treatment of the thyroid enlargement control the malady. It has to be treated upon general principles, just such general principles as would be applied to the treatment of any general neurotic affection.

In my experience physical rest is a point of very great importance. I do not believe that it is possible to treat these cases with any success without putting them to bed, and I am sure that that is a point of cardinal importance. Where the psychical phenomena are very marked, I think it is very desirable they should be treated as you would treat any melancholic patient; that they should be often sent away from home, and protected from surroundings which frequently aggravate the malady, for they are extremely sensitive to every disturbance. And inasmuch as they often arise from causes which are present in the home, the emotional disturbances which are incident to their surroundings, it is extremely important that they should be separated from them.

Next to the treatment by rest, I think that the dietetic treatment is important, for very often these patients suffer from innutrition and require very careful feeding, and this, in connection with passive exercise by massage and manipulations, I believe may often be of great service.

In regard to the treatment by drugs, I confess that there is in my experience, as there must have been in the experience of most of the members, a very large degree of dissatisfaction. I think that the use of cardiac tonics is often very beneficial. The one from which I have derived most satisfaction, I think, is digitalis and the class of cardiac tonics to which digitalis belongs. In using digitalis I have been in the habit of using it to get its effect upon the extremely accelerated and irregular action of the heart, and of giving it frequently in pretty large doses. I have used aconite in the form of the tincture and in the form of the active principle, aconitia, but have not had very good success with it. I think it is inferior as a heart tonic in these cases to digitalis. I have not had any experience with spartein, nor have I used strophanthus in these cases.

A remedy from which I have in some instances seen most beneficial results, and I have used it on the principle that it influenced markedly the heart's action, is iodide of potassium. This is a remedy, as you all know, which has long been used in this disease, its use being based in all probability upon its supposed power to diminish the thyroid enlargement. The first one in which I used it, thirty years ago, was one of the most marked cases which I have ever seen. It occurred in a woman about thirty-five years of age, who had a very large thyroid, most marked exophthalmus, and extreme rapid action of the heart. I used in her case iodide of potassium alone, and she made a perfect recovery in a few months, and is now perfectly well, leaving no trace of her disease. Another case I alluded to a few minutes ago, in a young woman of twenty-five, who had an extreme exophthalmus, a tolerably large thyroid, and very rapid action of the heart. She also recovered completely under the use of iodide of potassium. In that case, however, I also used small doses of digitalis. I have seen very excellent results in a considerable number of cases from the iodide, without complete cure, but I am sure that they were greatly relieved and the disease kept in abeyance and much benefited by the use of iodide of potassium.

I have had no experience with galvanism of the sympathetic, and I think from all that I have read upon the subject that the results of that treatment have not been such as to encourage its use.

Dr. Samuel Sexton asked Dr. Draper how frequent he had seen the pulse in Graves's disease.

Dr. Draper replied that he had counted it from 160 to 180. Again, he had seen cases in which the action of the heart was not extremely rapid, in which the other phenomena were present, and he thought there was this variability in all the symptoms. It was not very often that one saw all the triad of symptoms extremely marked. There might be a pulse of very moderate degree, with exophthalmus and thyroid enlargement, and the other phenomena which he had mentioned, and again there might be rapid action of the heart without much thyroid enlargement, and without much exophthalmus.

The Treatment Compared to that in Hysteria.—Dr. Francis Delafield said his own experience with the treatment of Graves's disease was much like that of Dr. Draper's. It seemed to him that, after all, one treated these patients very much as he treated cases of hysteria. As in hysteria, not only the treatment was of consequence, but also the person who directed the treatment; it was

not only what was done, but the person who did it. The practical management of the two diseases, hysteria and Graves's disease, seemed to him really very much the same.

Dr. Draper cited, in illustration of the truth of Dr. Delafield's statement of the necessity for a good adviser, a case where the disease had its origin apparently from emotional shock caused by the discovery of the infidelity of the husband. It began, it seemed, in disturbed cardiac action, and the other symptoms developed more slowly. There was a case in which it was perfectly plain how important it was for the patient to have a judicious adviser, who would look beyond treatment by drugs.

A Disease of Great Obstinacy.—Dr. Francis P. Kinnicutt had been impressed by the etiology which ascribed the disease to a neurosis and disturbance of the emotional nervous system, as had been claimed by many distinguished authorities; also by the kind of treatment which Dr. Draper and Dr. Delafield had found of importance. In his experience everything which tended to improve the morale of the patient was of just so much benefit. He had seen in the past year several cases in which that was conspicuous. The environment was such that, as long as it existed, in spite of every effort there was little improvement in the condition. With an entire change of environment, with the same medication (it was not a very pronounced one), certainly improvement did occur. But it was a disease of the greatest obstinacy, and where one got, as Dr. Draper had said, one or two complete recoveries, there were a great many cases that only partially recovered. The most distressing symptom, probably, aside from the psychical disturbance, was the extreme frequency of the heart's action, which was most common and most distressing. He thought that that was often benefited or completely disappeared, but the thyroid enlargement might remain after months and even years. He had been able to watch some cases through many years, in which the extreme frequency of the heart's action had entirely disappeared, and the psychical condition improved, but some fulness of the thyroid and some exophthalmus had remained. He believed that was the rule rather than the exception. He had seen two cases the past year, one in a boy of eight years, one in a young woman, in whom a change of environment caused a marked improvement. The extreme frequency of the heart's action quite disappeared, but the enlargement of the thyroid was just as marked as it was when they first came under observation. In a third case, that of a young woman of about twenty-five, the increased cardiac action and the thyroid enlargement quite disappeared under a change of environment, but returned when she came back to New York. She was advised to go away again, and to choose a quiet place, but instead, went to Bermuda, where she was under considerable excitement, and there did not improve.

Digitalis.—As far as drugs were concerned, he had found digitalis of more benefit in controlling the condition of the heart than any other. He had tried strophanthus and spartein and had come back to digitalis. He usually gave at the same time some preparation of iodine or bromides at the same time. He asked Dr. Draper and Dr. Delafield their experience with regard to the tendency of the symptoms in Graves's disease to recur, and in some cases to last a long time, measured by years.

Dr. Draper said, in reply to Dr. Kinnicutt's question, that he had had that experience. He had that day seen a lady who had developed this neurosis three or four years ago, and who, by the way, had an epileptic mother. She recovered after a few weeks' rest, and remained quite well. She then went to Europe, and when she returned had another attack. She recovered from this attack rather more speedily, under good care, digitalis, and iodide of potassium. She remained well a shorter period. He treated her early last fall, and recently she had had another attack, accompanied with extreme depression, and more symptoms of melancholia than he had ever seen before in this class of patients. In the attack previous to this one she had had a very exalted state of mind, was very much interested in society and in literary work, waking up at night and going to her table to write. As he had said, this subsided after she went away from the city, and she remained pretty well for two or three months, when she began to be depressed. This time she had not very rapid action of the heart, the pulse was not more than 80, she complained not at all of a sense of palpitation, but the exophthalmus was quite marked, and the thyroid enlargement was about as great as it had been.

Iodides.—He asked Dr. Delafield what experience he had had with the iodides. He supposed their action was much as in other affections of the heart, in asthma, etc., and it seemed rational to suppose that they would affect the cardiac symptoms favorably in these cases.

Dr. Delafield replied that he had used iodides, and he had used other drugs, but must confess that the thing which had always seemed to him of most importance was the management of the patient rather than the drug. For instance, if one compared the results in patients seen in private practice who could be managed, with that in patients seen at outdoor clinics who simply got the drug treatment and nothing else, he would be struck by the greater benefit effected in the former class.

Dr. Draper said he had seen some such marked results from iodide of potassium that he could not help having some faith in it as a drug in its action upon the circulation.

Dr. Delafield added that the action of the iodide of potassium upon the heart was often better than that of any other drug, but that, he thought, brought one to cases on the border line which it was difficult to be sure about. It seemed to him we got the best results from iodide of potassium in cases which had the rapid heart action alone, and those were just the cases which we could not be sure were cases of Graves's disease at all.

Dr. Draper asked Dr. Delafield further whether he did not think that Graves's disease spread itself out over a pretty large area.

Dr. Delafield replied that he would go even further, and say that he would not be sure that Graves's disease was a disease; that it had an entity; whether certain cases which we were in the habit of grouping together for convenience belonged to the same class, to the same disease. Regarding the obstinacy of these cases (the question raised by Dr. Kinnicutt), he said some patients would get better, and we knew no particular reason why they should; others whom we thought should get better would show no improvement. Again, there would be relapses, perhaps without apparent cause. In short, the cases were very capricious. There were plenty of cases which did not get better at all.

Dr. Kinnicutt said he had recently looked over the statistics, and had been somewhat surprised at the number of deaths which had been attributed to Graves's disease, cases in which the triad of symptoms existed.

Dr. Draper said that a number of cases of organic heart disease presented in their course some symptoms of Graves's disease. He then had a case of aortic obstruction and insufficiency in the hospital who had very prominent exophthalmus, no enlargement of the thyroid, but very rapid action of the heart. The man had just the appearance of a case of Graves's disease.

Dr. Kinnicutt added further that the usual cause of death seemed to have been marasmus, or suffocation from pressure of the thyroid on the trachea. As to treatment by rest, most benefit from this measure had been observed in cases in which the cardiac symptoms were prominent. Such cases, if allowed to go about in their usual way, seldom improved in any marked degree. Within the last day or two he had seen a woman, who, fifteen years ago, when under Dr. McLean, had a very marked attack of Graves's disease, with the triad of symptoms. After a number of years the triad of symptoms disappeared. He was asked to see this woman last

autumn, and while there was no indication of the old trouble, and no evidence of organic heart disease in the form of murmur, enlargement, or displacement, yet the heart's action was remarkably irregular. It was evidently a neurosis. The patient was able to drive out, and played croquet, yet her case was the most marked one of persistent irregularity of the heart's action which he had ever seen.

Galvanism at the Salpêtrière.—Dr. C. L. Dana, having just arrived, made some remarks upon the therapeutics of Graves's disease. He said he had passed through the wards of the Salpêtrière, Paris, last summer, and was told that Charcot taught that galvanism was the leading therapeutic agent. Although other things helped yet they relied chiefly on galvanism, which, if used persistently, would usually render the patient fairly comfortable. Dr. Dana's experience with this agent had not been quite so favorable, although he had seen good result from it, and there was no doubt but what it would, for a time, lessen tachycardia and some other symptoms. He had also seen some good results from iodide of potassium, but he had seen cases apparently cured by hydriodic acid in which the iodide had failed to give relief. A method of treatment which he had employed with a good deal of success, at the post-graduate clinic, was forced respiration. Credit was due to a lady physician of this city, Miss Bryson, for having observed that in the majority of cases of Graves's disease there was markedly diminished respiratory expansion, the patients being unable, after most persistent efforts, to expand the chest much more than half the normal. Dr. Dana had observed this fact in many cases. When he mentioned it to Charcot's assistant, he said he had not noticed it, but Dr. Dana was able to demonstrate it on the first patient shown him. Taking advantage of this observation his treatment had consisted in part of systematic respiratory gymnastics. He did not think there was any single agent which could be relied upon in all cases, but with the use of both drugs and hygienic measures he thought there were very few cases which could not be improved.

The President had obtained little benefit from cardiac tonics, such as digitalis and strophanthus. As to iodide of potassium, it seemed to him that the principal benefit was from the potassium rather than from the iodine, and that the bromide, for that reason, was about as useful as the iodide.

Dr. Dana said that many in the city had claimed to obtain benefit from carbacetate of ammonia.

Therapeutic Hints.

Chancroids.—Antifibrine is recommended as an efficient substitute for iodoform in the treatment of chancroids and also as an application to hard chancres, possessing the unquestionable advantage of being free from odor.

Interstitial Hepatitis.—Dr. Luigi Toralbo, writing in the *Gazzetta Medica di Roma*, recommends the employment of potassium iodide and the observance of a modified milk diet in the treatment of cirrhosis of the liver.

Treatment of Fracture of the Lower End of the Radius.—Dr. P. S. Conner, of Cincinatti, writing in the Fort Wayne *Journal of the Medical Sciences*, advises the treatment of fractures of this kind with a simple wristlet or an adhesive plaster band, which, he says, gives comfort by its steadying action, and at the same time answers the purpose as well as any other dressing in limiting the spreading of the wrist which results from the tearing loose the fibro-cartilage and its necessarily more or less imperfect reattachment to the ulna. In a few cases in which he has employed this method, discarding splints, he has been well pleased with the results obtained. In order to insure the success of the procedure, however, it is absolutely necessary that not partial but complete replacement of the fragments be primarily effected.

Vinegar in Croup.—Dr. S. J. Bumstead regards vinegar as a very valuable therapeutic resource in catarrhal and membranous croup. He uses it in the form of vapor, pouring the liquid into a bread-pan and then putting into it bricks or flat-irons heated in the stove. In this way the room soon becomes filled with a cloud of acetic vapor. He also employs internal medication, but looks upon the vinegar inhalations as of first importance in the management of the disease.—*North American Practitioner*, May, 1891.

Etherization in Croup.—Dr. Friedrich Betz reports, in *Memorabilien* for April 18, 1891, a case of croup in a child aged thirteen months, who was apparently moribund when seen, in which recovery followed the inhalation every 15 minutes of 3 drops of a mixture of 1½ grain of menthol, 15 minims of acetic ether, and 45 minims of sulphuric ether. He says that in another similar case he would increase the quantity of menthol to about 5 grains—the amount of the mixture inhaled being increased proportionately to the age of the child.

The Internal Use of Resorcin.—Resorcin has not been employed to any very great extent as an internal remedy, its use being chiefly confined to external applications. Dr. H. Menche has, however, been giving it in many internal disorders for a number of years, and reports his results in an article in the *Centralblatt für Klinische Medicin*, No. 21, 1891. His first essays were made in cases of cholera infantum, for which he gives a prescription containing from five to seven grains of resorcin in three ounces of simple syrup and water, a few drops of compound tincture of gentian or, if thought necessary, a minute quantity of laudanum being added. In cholera nostras also good results were obtained, the vomiting being speedily controlled and the patient making steady progress toward recovery. The author holds that resorcin is indicated in all forms of gastritis, in the dyspepsia following indiscretions in eating or drinking, in acute and chronic gastric catarrh, and in rumination. In acute ulcer of the stomach, however, the drug is contra-indicated. In the vomiting of pregnancy, in sea-sickness, and indeed in all forms of vomiting, from whatever cause, Dr. Menche recommends resorcin as of undoubted utility. He also used it with apparently good effect as an hypnotic in a few cases. The remedy was given in solution or in powder, the dose for adults being from one and a half to two grains every two hours. As an hypnotic he is in the habit of ordering a single powder of seven and a half grains at bedtime. For sea-sickness he gave one or two grains in sugar of milk every two hours, and reports some very successful cases of this treatment. Of course, he insists upon the necessity of obtaining a perfectly pure specimen of the drug in order to secure the results desired.

Dog's Blood Serum in Tuberculosis.—Some French observers have recently made a number of experiments with the injection of the blood serum of dogs in cases of tuberculosis of the lungs and larynx, and report that the measure appeared to have been beneficial. The appetite was improved, the cough and night-sweats ceased, and the patients increased in weight. The amount of serum used each time was from one-half to three-fourths drachm, and the injections were made in the lumbar region once in two or three days.

Tincture of Iron in Bright's Disease.—Dr. Wyss employs the ethereal tincture of the perchloride of iron, in doses of ten drops three times a day, in the treatment of chronic Bright's disease. He reports a large number of cases so treated, in more than half of which the albuminuria rapidly and completely disappeared.

Chloralamid in Surgery.—Dr. Emory Lanphear, of Kansas City, regards chloralamid as an excellent hypnotic, when such a remedy is needed after a surgical operation. He gives from fifteen to thirty grains, dissolved in whiskey, repeating the dose in an hour if the first have not produced the desired effect. He suggests the following as a good formula for the exhibition of the drug :

℞. Chloralamid ..... ʒ ij.
Spts. frumenti ..... fl ʒ j.
Misce bene et ft. solut. et adde :
Syrupum rubi idæi ..... fl ʒ j.
Misce. Sig. : Dose, one tablespoonful, to be repeated in one hour if sleep is not produced. This makes a decidedly pleasant mixture of slightly acid taste and fruity aroma and flavor.

Hæmoptysis.—The following is recommended as useful in hæmoptysis when the loss of blood is slight but persistent :

℞. Turpentine,
Oil of sweet almonds ..... āā ʒ j.
Mucilage of acacia,
Simple syrup ..... āā ʒ iv.
Distilled water ..... ʒ v.
M. S. : One teaspoonful every half hour.

Rhus Poisoning. — A lotion of three drachms of powdered ipecac in a pint of water is recommended very highly by Dr. W. S. Gilmore, in the *Country Doctor*, as an application in the dermatitis caused by poison ivy.

Styracol is the name of a recently introduced antiseptic. It is said to be a cinnamic ether of guaiacol, and is prepared by mixing equal parts of guaiacol and chloride of cinnamyl, warming and adding boiling alcohol. When the mixture cools, needle-shaped crystals of styracol are deposited. It is said to be of value internally in catarrhal conditions of the alimentary and genito-urinary tracts.

Sea-salt for the Relief of Insect Stings.—Rubbing the parts with sea-salt, dampened with a little water, is efficacious in relieving the distress caused by stings from wasps, bees, and other less formidable insects. The pain and swelling quickly subside after such an application, and if the salt be applied at once these phenomena will usually not appear.

To Promote the Absorption of Iron.—Essential oil of thyme made into a pill with soap and althæa is reported by Dr. Gros to aid the digestion of iron in anæmia and chlorosis. The daily dose is 2 minims, divided into three pills, and to be taken after each meal.

Ingrowing Toe-nail.—Dr. Pürckhauer recommends the following method in the treatment of ingrowing toe-nail : A forty per cent. solution of potassa is applied warm to the portion of the nail to be removed. After a few seconds the uppermost layer of the nail will be so soft that it can be scraped off with a piece of sharp-edged glass : the next layer is then moistened with the same solution and scraped off ; this must be repeated until the remaining portion is as thin as a sheet of paper, when it is seized with a pincette and lifted from the underlying soft parts and severed from the other half. The operation does not require more than half an hour's time, is painless and bloodless, while the patient is delivered from his suffering without being disabled even for an hour.—*The Pittsburg Medical Review.*

Cocoanut for Tapeworms.—A whole cocoanut grated fine and taken with its own milk, on an empty stomach, in the morning, has been said to cause the expulsion of tænia. This item appears periodically in the medical press, but we have never heard of an authentic case of relief by the measure suggested.

Pineapple Juice is said by someone to be of remarkable efficacy, internally and locally employed, in diphtheria. Perhaps it is.

For Vomiting in Pregnancy the painting of the cervix uteri with a solution of cocaine has been recommended.

Bananas in Chronic Bronchitis.—In cases of chronic bronchitis with difficult breathing and scanty expectoration the use of banana-juice has been highly praised. The juice is prepared by cutting up the bananas in small pieces and putting them, with plenty of sugar, in a closed glass jar. The latter is then placed in cold water, which is gradually made to boil. When the boiling-point is reached the process is complete. Of the sirup so made a teaspoonful every hour is the proper dose.

Wiring the Vertebræ.—Dr. B. E. Hadra, of Galveston, Tex., reports, in the *Times and Register* for May 23, 1891, a case of fracture of the neck in which immobilization was secured by wiring together the spinous processes of the sixth and seventh cervical vertebræ. The patient was not cured at the time of the report, yet the operation had seemingly proved the feasibility of the method in similar cases. Dr. Hadra suggests that the same procedure might be of great utility in cases of Pott's disease of the spine.

Sea-salt in Headache.—Dr. Leslie recommends nasal insufflations of sea-salt in neuralgic and other forms of cephalalgia.

Caffeine in Post-partum Hemorrhage.—Dr. Misrachi, of Salonica, writes, in the *Bulletin Général de Thérapeutique* of May 15, 1891, concerning the value of hypodermic injections of caffeine as an adjuvant to ergot in the treatment of post-partum hemorrhage. While the ergot acts upon the uterine muscle, stimulating it to contract, the caffeine tends to obviate the evil consequences of the hemorrhage, cerebral anæmia, cardiac weakness, etc. Of course no drugs will be of service when the hemorrhage proceeds from mechanical causes, such as retained portions of placenta and the like.

Inhalation for Acute Coryza.—Hayem has found relief, though seldom cure, follow inhalations of carbolic acid and ammonia. He recommends the following formula :

℞. Pure carbolic acid,
Water of ammonia ..... āā ʒ j.
Alcohol ..... ʒ ij.
Distilled water ..... ʒ iij.
Sig. : Pour a few drops on thick blotting paper and inhale the fumes for a few seconds.

Thymus Vulgaris in Whooping-cough.—Dr. A. Neovius reports, in the *Finska Lakaresällapets Handlingar* for March, 1891, very successful results obtained during an epidemic of pertussis by the exhibition of a syrup of garden thyme. He made a decoction of one part by weight, of sweet thyme in seven parts of water, to which was added five parts of sirup of althæa. Of this mixture, from a teaspoonful to a tablespoonful was given eight to ten times a day. The only unpleasant symptom caused by the drug was a slight diarrhœa in most cases. The relief afforded was prompt, the cough soon losing its spasmodic character, and assuming the form of a mild catarrhal bronchitis.

Charges against a Doctor.—The Consulting Board of Physicians of the Soldiers' Home at Noroton, Conn., has preferred charges against Superintendent and Resident Physician-in-Chief B. W. Munson, and forwarded them to Governor Bulkeley, with the recommendation that he be removed from the office of Physician-in-Chief. The testimony was to the effect that Dr. Munson is away from the Home a great deal, that he neglects his duty by failing to visit the wards as the rules prescribe, that he has refused to fill requisitions for medicines and other supplies, and that he neglects the patients.

New Instruments.

A NEW SPRAY TUBE.

SPECIALLY DESIGNED FOR THE APPLICATION OF MEDICATED OILS AND FATS TO ANY PART OF THE RESPIRATORY TRACT.

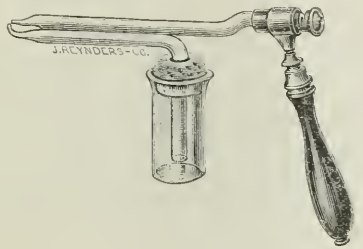
BY A. N. STROUSE, M.D.,

INSTRUCTOR IN OPHTHALMOLOGY, NEW YORK POLYCLINIC, ETC.

ON looking over the various vaseline and oil sprays I found that none of them could conveniently be connected with the compressed-air apparatus, and with this object in view I designed the appended spray tube.

The tube itself is but five inches in length, having a fine point drawn out only about one-half inch (instead of one inch or more, as is usual with the Sass tubes), thereby insuring strength and rendering it less liable to break.

The handle fits over the bayonet attachment, and is removable by unscrewing it one-half a turn, and thus it can rapidly be taken from one tube and put on to another, even while the tubes are in the spray-rack, one handle being sufficient for any number of tubes. The handle is set at an angle, overcoming some of the objections of application in stout persons.



In using vaseline or solid oils, or if it be desirable to warm solutions before applying them, one can readily see how nicely these may be heated, without burning or soiling the fingers, for we take them out of the rack by the handle and not by the tip. The spray thrown from this tube is very fine and light, and can be inhaled into any part of the respiratory tract. Tubes with an upward or downward tip can be made—and should be one inch longer—but are considered unnecessary, for it is soon evident that the spray, when blown through the nares or into the mouth, passes into the trachea without any inspiratory effort on the part of the patient, evidenced by a fine cloud coming from the patient's mouth on expiration. I now use these spray tubes for all medicated sprays in preference to others, as they are handier, there is less loss of liquid, and the hands are secure from staining.

For those who do not use the compressed-air apparatus Messrs. Reynders & Co., 303 Fourth Avenue, who have made the tubes for me, will furnish a double bulb with stop-cock attachment, and a stout covering over the receiving bulb, an instrument I have used for a number of years, and which has filled the place of the compressed-air apparatus admirably.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 28, 1891, to July 4, 1891.

SKINNER, J. O., Assistant Surgeon. Upon the abandonment of Fort Davis, Tex., will proceed to Fort Clark, Tex., and there take station.

EWING, C. B., Assistant Surgeon. Granted leave of absence for one month.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July, 4 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	2
Scarlet fever	102	24
Cerebro-spinal meningitis	0	3
Measles	188	16
Diphtheria	56	21
Small-pox	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

An Ounce of Prevention.—People are willing and eager to speak in warmest praise of the physician who has brought them safely through some awful crisis of disease; and rightly. But how seldom do they recognize or appreciate that greater skill which detects disease in its early stages, and so promptly and wisely treats it that the patient does not go down into the shadow of death, says the *Healthy Home*. The greatest skill is habitually displayed in treating the every-day ailments, so commonly regarded as trivial and unimportant; and almost every physician of large experience will tell you that much of his best work passes unrecognized and unthought of. Indeed, his greatest, many times his only, reward comes from the consciousness of a good work well done.

The Qualifications of a Physician in Olden Times.—A statute of Henry VII. ordains that the practice of the healing art shall be limited to those persons that be profound, sad, and discreet, grandly learned, and deeply studied in physic.

"We Get There Just the Same."—The world cannot have too much of good poetry, and we venture to quote some verses contributed to the *Hospital Gazette*:

Our lip we can't help curlin'
At the medical profesh:
Sure, there's Dr. Quack, of Berlin,
Always finding something fresh
To prevent mankind from croaking,
And to load himself with fame.
This is not a theme for joking,
But—we get there just the same.

. . . . . .

Here's a man has struck a plan, sirs—
So the daily papers say—
To prevent the growth of cancers,
And we only hope he may;
All the things they'll soon be healing
To which one can put a name—
Yet we're haunted by a feeling
That we'll get them just the same.

Oh, confound all foreign "masters"
With a secret to disclose!
We believe in mustard-plasters,
And put tallow on our nose.
Let the savants of Vienna
Spin their narratives so lame—
If we stick to salts and senna
We can get there just the same.

The von Reinecker Prize.—A prize of the value of $2,500, and a gold medal, has recently been established by Professor von Reinecker, of the University of Würzburg, to be awarded every three years to the author of the most important discovery in medicine during that period. The first prize has just been awarded to Koch.

The Wearer of Diamonds, according to Pliny, was secure against insanity.

THE CORRECTION OF ANGULAR DEFORMITIES OF THE NOSE BY A SUBCUTANEOUS OPERATION.[1]

By JOHN O. ROE, M.D.,

ROCHESTER, N. Y.

At a meeting of this Society four years ago I presented, as you may remember, a paper on "The Deformity termed Pug-nose, and its Correction by a Simple Operation."[2]

It is my purpose to describe to you, in this short paper, an operation for the correction of angular deformities of the nose by a subcutaneous operation. This is an operation for the correction of a condition directly opposite to that deformity which formed the subject of my previous paper, and is applicable not only to the correction of angular deformities of congenital origin, but to the deformities resulting from injuries as well.

In all surgical operations about the face, it is as necessary to avoid mutilation of the skin as to correct deformity, since in many instances an operation might otherwise simply result in exchanging a deformity for an unsightly blemish. It is for this reason that many deformities of the face, and particularly of the nose, are allowed to go uncorrected, which are a *marque de reconnaître* for every one who sees them, and a constant source of annoyance to the persons themselves.

In describing the technique of this operation I cannot make it more clear than by briefly reporting some cases in which I have performed the operation. Miss C— , aged twenty-five, consulted me for a "winter cough," which was giving her much concern. While she was under treatment she often referred to her nose, and complained about an angular, bony projection on its top that not only gave her nose an unsightly shape, but so pierced the skin as to make it painful for her to wash or wipe her face. She was quite desirous of getting rid of this annoying projection, but was afraid an operation might leave an unsightly scar. In order to avoid this possibility I suggested that the projection be removed by an incision from the inside of the nostril without wounding the skin, and this suggestion at once induced her to have the operation performed.

After anæsthetizing the part with cocaine, both by applying it to the interior of the nostril and by injecting some under the skin with a hypodermic syringe, I made a lineal incision completely through the upper wall of the left nostril, just in front of the nasal bone, between it and the upper lateral cartilage of the nostril, to the under side of the skin. This incision I widened laterally from the insertion of the upper border of the triangular cartilage half way down the side of the nose, until I had a sufficiently large opening to permit the introduction of instruments freely. I then raised the skin from the bridge of the nose over the region where the operation was to be performed. After the skin was sufficiently freed from the top of the nose I inserted a pair of angular bone-scissors and cut off the projecting piece of bone until the top of the nose was perfectly straight and smooth. The operation was done with the strictest antiseptic precautions, and after completion I blew in some iodoform powder, through the opening, over every portion of the wounded surface. The skin was then allowed to drop back upon the bridge of the nose, and, by strapping it down with gentle pressure, the wound healed without the slightest formation of pus, and there was very little soreness. There was no mutilation of the interior of the nose, for even directly after the operation it was difficult to detect, by simply inspecting the interior of the nose, the incision that had been made. In a few days the nose was entirely healed, and the soreness had disappeared when the patient left for her home. About six weeks afterward she wrote me that she was highly delighted with the result. She no longer had to be constantly on her guard lest she should allow something to come against her nose, and she said that it felt as if she could beat it against a stone wall without hurting it.

FIG. 1.

FIG. 2.

Figs. 1 and 2 represent the appearance of the nose from photographs taken before and after the performance of the operation.

The second case was that of a young lady on whose nose I operated for a similar deformity, and in the same manner, and with a like excellent result. See Figs. 3 and 4,

[1] Read before the Medical Society of the State of New York, February 6, 1891.

[2] MEDICAL RECORD, June 4, 1887.

which are also from photographs taken before and after the operation.

The third case, an exceedingly interesting one, was for the correction of a deformity, resulting from an injury, the details of which are as follows: Mr. M——, a gentleman residing in a neighboring city, was out one day on horseback. His horse, being very spirited, sud-

Fig. 3.

Fig. 4.

denly shied at a piece of paper flying in the street and threw him violently to the ground, directly under the horse's feet. The horse at the same time struck him with a shoe cork of one of its forefeet, directly in the centre of the top of his nose, producing a very severe fracture. His family physician, who was an excellent surgeon, was at once called. He found the nose so badly broken up that portions of the nasal bones were lying loose in the gaping wound. These he picked out, and after thoroughly cleansing the wound, brought the different portions of the lacerated skin together as well as possible, and carefully applied an antiseptic dressing. The following day the doctor telegraphed me to come and see the patient. I found the nose in as good shape as circumstances would permit. The vomer was, however, broken and crowded out of place. The swelling of the nose and face was by this time so great that it was not advisable to attempt any active interference lest it should prevent or disturb the healing of the lacerated skin.

In about five days the swelling had so much subsided that the real condition of the nose was apparent, and he then came to Rochester for further treatment. The septum was put in place, and held there by means of metallic splints wound with cotton; but it soon became apparent that the support to the bridge of the nose was so completely undermined, the lower portion of the nasal bones being destroyed, that the nose was quite sure to fall in, unless proper support could be applied at the right spot from the inside. The plan of transfixing the nose with pins to hold it up in place could be of no avail in this case, so the following plan was resorted to: A piece of brass spring wire was bent to form a spiral spring as shown in the illustration (Fig. 7). One arm was bent to lie along the floor of the nose; the other was bent to fit under the bridge of the nose. These arms were covered with snugly fitting rubber tubing, so as to make them soft and to prevent erosion. The arms were bent together before insertion, but when allowed to open they exerted an upward pressure, with the floor of the nose for the fulcrum or support. One of these springs was inserted into each nostril. This plan worked admirably. It kept the bridge of the nose elevated as high as the amount of tissue left would permit until the broken septum had become firm and the other parts healed so that the nose was self supporting.

This patient, before the accident, had a fine Grecian nose, but the loss of a large portion of the nasal bones converted it into *le nez retroussé*. The nose was, however, rendered very unsightly and conspicuous by the angular projection of the stumps of the nasal bones, where they were broken by the horse's shoe.

The operation for the removal of this projection was deferred for several months, in order that the nose might become thoroughly healed and firmly fixed in position.

Fig. 5.

Fig. 6.

On June last, the operation for the removal of this projection was made. As an impediment to the operation, however, there was the scar in the skin that had become firmly adherent to the bone at the seat of the injury. This was thought to be an insurmount-

able obstacle to the success of my proposed operation.

I made an incision, similar to that described in the previous case, through the upper wall of the nose from the inside, to the under side of the skin; then, with a very delicate knife, having a round, slender shank, I very carefully dissected this adherent skin from the bone, without cutting through the skin at any point. After the skin was raised from every portion to which it had become adherent, and also from that portion which was to be removed, I cut and drilled away the bone down as far as desired. The operation was done antiseptically, so that no inflam-

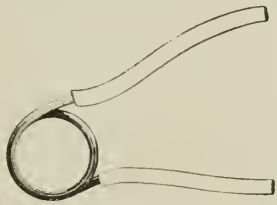

FIG. 7.

matory trouble followed, and the result was satisfactory in the highest degree. The skin has remained free and movable over the bone, and the scar of the skin is scarcely visible. The use of cocaine locally to the nostril and injected under the skin rendered the operation quite painless.

The patient, as you will observe by the cut (Fig. 6), which is from a photograph recently taken, has a very presentable nose, quite as good as could be hoped after so severe an injury. Fig. 5 represents the appearance of the nose before the operation.

Since the above-described operation was performed I have operated on two patients for angular deformity of the nose, with most excellent results in both cases. In one case the deformity was congenital; in the other it was the result of an injury incurred when the patient was quite young.

For the performance of this operation the application of cocaine to the interior of the nose, and injected under the skin is, in nearly all cases, sufficient to render the operation quite painless, although general anæsthesia can be employed should it for any reason be necessary.

This operation is readily seen to be of great value in the correction of all kinds of angular deformities of the nose, from whatever cause, since it avoids all necessity of wounding the skin, and no after-treatment is required, other than the use, for a short time, of a light compress or bandage over the seat of the operation.

ONE THOUSAND CASES OF OCULAR HEADACHES AND THE DIFFERENT STATES OF REFRACTION CONNECTED THEREWITH.

BY W. F. MITTENDORF, M.D.,

NEW YORK.

THERE is hardly a subject in medicine that has received more attention of late than the effect of eye-strain upon the nervous system, and especially its connection with headache.

This same subject has been known and spoken of by ophthalmologists as asthenopia for many years. At first, as early as fifty years ago, it was thought to be almost entirely due to fatigue of the external muscles of the eye, and this view has been more recently brought forward again with much enthusiasm.

However, since Donders's publications on the subject, errors of refraction have been recognized as the main cause of the long list of complaints known under the same name of asthenopia. Of all the symptoms of this condition headache is the most prominent and the one most frequently met with. So many papers on ocular headaches have been published of late, that every practitioner begins to appreciate the value of correcting-glasses; but even now patients are dosed with medicines and treated for indigestion or malaria for a long time before an examination of the eyes will reveal the true cause of the affliction.

The object of this paper is principally to point out the frequency of certain errors of refraction met with in these cases, and to endorse the views of such writers as Drs. Roosa, of New York; Javal, of Paris; Chisholm, of Baltimore, and many others, to the effect that the external muscles of the eye play a very insignificant rôle in the causation of headaches, in comparison with errors of refraction, and chief among these, "astigmatism."

The number of cases of ocular headache which have come to my office for treatment has been so large that I have been able to select a thousand which were not only due to eye-strain, but were more or less completely relieved by the proper glasses, in only a little more than the last two years.

In our hospitals and dispensaries cases of this kind are not so frequently met with as in private practice, as patients visiting these institutions are not so apt to use their eyes so much for reading and studying as private patients do. Among my patients the number of school-children and college-students has been unusually large, likewise that of ladies who had little or no out-door exercise, and whose muscular system was, as a rule, not as well developed, as it would have been had they had more of this kind of exercise. In speaking of the muscular system I do not refer exclusively to the external muscles of the eye, but more to the general system, as it is my experience that the muscles of the eyes, especially the all-important ciliary muscles, are more or less in harmony with the other muscles of the body, and I am therefore very careful in the treatment of my patients to lay a great deal of stress upon the usefulness and importance of gymnastic exercise. I have had more young patients complaining about their eyes who did not have a chance to enjoy the benefits of a regular gymnastic training than those visiting schools where a daily attendance at the gymnasium was required, or who belonged to some regular athletic team.

A number of these patients would be entirely free of headaches and lay aside their glasses as soon as they were able to devote a good deal of time to gymnastic sports, but were obliged to use glasses or suffer from headaches when their school work kept them confined to their books. It is a well-known fact that many people with well marked errors of refraction, especially such as hypermetropia and astigmatism, will go through life and not experience the slightest inconvenience therefrom; but if from some cause or another their health becomes impaired or they abuse their eyes, asthenopic troubles are liable to come on and may become so marked as to unfit them for business or to force them to leave school or college, and to make their life miserable otherwise. In some cases the distress is so great and continues for such a length of time that a few of my patients told me that they had thought seriously of committing suicide if their troubles could not have been relieved.

The errors of refraction of the one thousand cases were as follows:

Myopia, 20, or two per cent.; myopia and astigmatism, 8, or about one per cent.

Simple myopic astigmatism, 111, or eleven per cent. Of these 60 were of 0.5 D., and 5 were of 0.25 D.

Hypermetropia, 78, or eight per cent.; hypermetropia with presbyopia, 35, or three and a half per cent.; hypermetropia with astigmatism, 67, or seven per cent.

Simple hypermetropic astigmatism, 626, or nearly two-thirds. Of these 116 required more than 0.5 D., 230 required a 0.5 D., 261 required only a 0.25 D. cylindrical lens.

Anisometropia, 27, nearly three per cent.

Mixed astigmatism, 21, or two per cent.

Emmetropia with muscular faults, 7, or hardly one per cent.

To recapitulate: Myopia furnished two per cent. Hypermetropia (including some cases with existing presbyopia) eleven per cent.

Astigmatism of all kinds, eighty three per cent. Of these 119 were myopic, and nearly 700 were cases of hypermetropic astigmatism.

Of patients requiring a cylindrical lens of one-half or one-quarter of a diopter, we have 60 of the former and 5 of the latter in myopic astigmatism, and 230 of the first, and the great number of 261 cases of the second, in the hypermetropic variety. The axis of the cylinder in the weaker glasses in hypermetropia was as follows:

Axis at 90°, or nearly so, 418 times; axis oblique in 40 cases, and at 180° only 33 times. In myopic astigmatism axis at 180°, 80 cases; at 90°, 21 cases; and oblique, 10 cases.

In hypermetropic astigmatism the axis was most frequently perpendicular, or at 90°; in the myopic variety horizontal, or at 180°.

In the seven emmetropic cases the asthenopia was due to an anomaly of the muscular apparatus, which called for the use of prisms or for operative interference. This number, however, does not include the cases of squint which presented themselves for operative interference.

The eyes of the patients were all perfectly healthy in every other respect.

It is impossible to go into the details of many of these cases, although there are a great number of them not only of great interest but also of some importance. The great frequency of astigmatism is very apparent, and greater in proportion than in any number of cases that I have seen reported. This is probably due to the fact that I have employed so many weak cylinders. But it is just among these cases that the most distressing symptoms have been met with, and many patients with headaches—frontal, supraorbital, temporal or occipital, the pain extending often from the back of the head along the spinal column—disturbance of the stomach, producing at times nausea and even vomiting, pain extending even to the limbs, twitching of eyelids, distressing nictitation and even choreic movements of the face, depression bordering on melancholia, and other troubles which are usually classed as general nervousness and which had baffled the skill of the family physicians, were often promptly relieved by a weak correcting cylindrical lens.

Many of the patients with the lesser degrees of astigmatism could hardly believe that their eyes were at fault, and would frequently begin by saying that their family physician must be mistaken to send them to an oculist; they were sure their eyes were so perfect that they could not be the cause of the distressing headache they had for such a long time. This belief of astigmatics that their eyes are perfect is due to the fact that in most of the cases of the lesser degrees of astigmatism the patients have perfectly normal vision for the distance, and they can often use their eyes for near work for a long while without feeling any unpleasant symptoms at the time, the pains coming on some time after using the eyes, or perhaps only the next morning, or even only the latter part of the week, and not unfrequently only on Sunday mornings; this is apt to be the case in conscientious housekeepers, who work so hard during the preceding Saturday preparing everything for Sunday, that the eyes as well as the rest of the body get thoroughly fatigued. I have had quite a number of cases of this kind, where a cylindrical glass led to the cure or to the prevention of Sunday morning headaches, which had existed regularly for many years and which had been ascribed to some obscure malarial influence.

On the other hand, we meet with similar cases of astigmatism of perhaps a half or a quarter of a diopter only, where the eye symptoms are quite marked and come on immediately after the least effort to use the eye for reading or writing. I remember, for instance, the case of a lady who could do light housework all day and feel comfortable, but if she attempted to read even a short letter, she would at once get a violent headache, and it would take her a week or more to finish writing a letter. She could write only a few words at a time, when she had to stop on account of pains and feel tired as if she had done a good day's work.

A unique case is that of a lady in Rochester, who could not read or write, nor go to receptions or theatres without paying dearly for it. She had her eyes examined several times, had been under the care of a gynecologist, and it was under protest that she entered my office. She had perfectly normal vision of each eye, a perfect nerve and fairly proportioned muscles, the internal recti overcoming a prism of 18°, and the external recti one of 7°. She refused all glasses with the exception of a cylinder + 0.25, which not only rested her eyes for the distance, but enabled her likewise to read the fine print of a newspaper for fifteen minutes at her first visit. Several weeks after her return home she wrote me a very pleasant letter with the news that she had had only one slight attack of headache, which came on after addressing over three hundred invitations in one afternoon. She could go out as much as she wanted to without any trouble, and was only surprised that so weak a glass could give her such comfort. This was nearly eighteen months ago, and lately she informed me that she had become more and more independent of her glasses, and used them only when she was going to have a good long read.

Another class of cases are met with in students, where the symptoms are so distressing that they often have to leave college for a long time. During the time that I was connected with the Bellevue Hospital Medical College I would frequently have as many as half a dozen of the students, during a term, suffering from very intense asthenopic symptoms, which were often relieved by a correcting cylindrical lens of one-half or a quarter of a diopter. The appearance of the asthenopia in these cases is easily explained by the fact, that many of the students are young men from the West or South, who after living most of the time in the open air suddenly change their entire way of living; boarding in a cheap, city boarding-house, they spend most of their time in poorly ventilated lecture-rooms, and their evenings in poorly illuminated rooms over their books. This lowers their muscular power sufficiently to interfere with their power of accommodation, and a small amount of astigmatism, which gave them no trouble whatever before, because their accommodation easily overcame it, becomes now a source of much distress.

Still another group of cases of this kind which I have often met with are those in which excitement in conjunction with unusual fatigue of the body brings on headache, which, after all, is only due to irregular action of accommodation in astigmatic eyes. Some persons, especially ladies, are apt to get these headaches after shopping expeditions, or after balls and receptions, where they have to remain standing sometimes for hours.

It appears that astigmatism of even a slight degree leads at times to such distressing asthenopic symptoms on account of the irregular action of the ciliary muscle required for its correction, which is more fatiguing and irritating than a much greater but evenly exerted effort of this muscle, and partly because on account of the slight amount of disturbance produced at the time the effort is persisted in for a long while, thus giving the irritation ample opportunity to affect many nerves, in fact not infrequently the entire nervous system, and possibly even the vaso-motor nerves, giving thus rise to disturbance of circulation and hyperæmia of the retina and optic disc. As a rule the irritation remains peripheral, for I have not met with, nor heard of a case where other nerves of cranial origin (such as the auditory, olfactory, or facial nerves) became involved, with the exception of those nerves more or less connected with accommodation and convergence.

The diagnosis of the smaller degrees of astigmatism is not always easy. The ophtholmoscope is always the most reliable means at our disposal, and although it may not be possible to come within a quarter of a diopter of ametropia, yet it furnishes us usually the proof that the degree of irregularity does not exceed one diopter of either hypermetropia or myopia of the one meridian from that of the opposite. This is very important, for I firmly believe that in astigmatism of less than one diopter atropine should never be used, as it is not only misleading, but subjects the patient to unnecessary trouble and often great loss of valuable time.

It is often possible to prove the existence of even a quarter of a diopter of astigmatism by throwing the image of the fundus slightly out of focus by using a convex lens of a half or one diopter in the ophthalmoscope. By this manœuvre the emetropic meridian will be quite blurred, but that of the other one will be much clearer and distinct, at least so much so, that the existence of astigmatism is proven. In myopic astigmatism the reverse, a concave lens should be used in the ophthalmoscope, when the greater distinctness of the previously slightly indistinct myopic meridian will help us greatly in our diagnosis.

Atropine should only be resorted to in higher degrees of astigmatism, especially if the visual power cannot be brought up to the normal standard by glasses or if there is much spasm of accommodation present. In the lesser degrees of astigmatism it should never be used, as the results obtained are apt to be misleading, and I have often found that not only the strength but even the axis of the cylinder, determined under atropine, will not be accepted by the patient after the effects of the mydriatic have disappeared. This is not hard to explain, when we consider that an immensely dilated pupil may reveal irregularities of the more peripheral parts of the cornea which with a normal pupil are entirely excluded, and consequently are of no importance whatever. Neither can we rely absolutely on the radiating lines of astigmatic test-types, as they may appear perfectly distinct in all directions to the astigmatic eye, if there is only a slight degree of change of the normal curvature, which is fully corrected by the action of the muscle of accommodation. Sometimes it becomes possible to demonstrate astigmatism even in these cases if we release the extra strain of the accommodation by placing a convex lens of one or one and a half diopter power before the eye, when the patient will at once point out the lines remaining distinct and those that appear blurred.

I cannot emphasize the importance of looking for very slight degrees of astigmatism in connection with asthenopic complaints too much, for although a number of writers have recorded their experience in this respect, there is hardly a textbook on ophthalmology in existence, which recognizes this fact, and even in one of the most recent and most complete works of this kind, namely, that of Dr. H. D. Noyes, of this city, the author uses this expression, that even slight degrees of astigmatism of one-half of a diopter must not be neglected. The existence and great importance of only a quarter of a diopter of astigmatism is not mentioned at all, and yet it is this weak cylindrical glass of 0.25 D. which has been of such great service to me.

In some of my cases there may have been a little more of astigmatism than was represented by such a lens, but it evidently served to relieve that amount of extra strain placed upon the ciliary muscle, which had given rise to all the unpleasant symptoms of reflex irritation which the patient had complained of.

These very slight amounts of irregularity are not easily discovered by the retinoscopic tests, and only by a very experienced observer are they determined on Javal's ophthalmometer. Even the ophthalmoscope presents some difficulties in this respect, and it is principally the use of cylindrical lenses and the test-types that we have to rely on. There are usually some letters which have a similar shape such as O. C. G. and D. or B. and R. and F. and P. and T., and which present to the astigmatic eye some difficulties to recognize them from a distance of twenty feet or more in some cases. If these letters are not readily recognized with the naked eye, but promptly after the cylindrical lens has been held before it, and if, after changing the axis in various directions, the same axis is constantly preferred, we may be sure to have a case of astigmatism to deal with, and if all stronger convex, or in myopic astigmatism all weaker lenses are refused, the degree of the refractive error is determined at the same time. If the patient can use such a glass with perfect ease and comfort, for near as well as for distant objects, we are justified in ordering them, provided the ophthalmoscopic examination does not show any conflicting evidence.

In the treatment of these cases I do not confine myself to the selection of proper glasses, but pay great attention to the mode of living of the patient. Normal circulation and a proper amount of outdoor exercise exert a very beneficial effect upon patients who are often very nervous and not unfrequently very despondent and quite unhappy. There is, as a rule, no better auxiliary remedy than a proper amount of gymnastic exercise, and I firmly believe that were it not for the athletic societies at our colleges, the number of asthenopic patients would be much greater than what it is now. Ladies especially are often greatly in need of some regular gymnastic exercise. Of these fencing, boxing, and horseback-riding, especially the two former, are to be recommended, because in these the muscles of the upper part of the body are better trained, and even the muscles of the eyes are given healthy exercise in watching the opponent.

A great favorite remedy of mine is a stimulating lotion applied to the closed lids and forehead. This lotion is composed of lavender, rosemary, camphor, and alcohol, and acts as a mild counter-irritant. Conjunctival complications should be treated by applications of mild solutions of alum or acetate of zinc, or the biborate of soda. Attacks of intense pains may have to be relieved by proper doses of aconitia or phenacetin; in milder cases electricity acts sometimes very nicely, and not unfrequently the use of a general tonic treatment is indicated, of which, of course, the family physician is the best judge.

In conclusion I would like to state that, according to my experience, ocular headaches and other asthenopic symptoms are much more frequently, in fact, almost universally, due to fatigue of the internal, and not to irregularities of the external, muscles of the eye; although the latter may accompany or be the result of the errors of refraction. That for this reason a more careful inquiry into the lesser degrees of refractive errors and their correction is of the greatest importance; and that if this is done very few cases will remain where the use of prisms or cutting of the external muscles is indicated or needed. In fact, many a time have I had occasion to discard prisms, which had been prescribed, and substitute weak cylindrical lenses for them with the most gratifying results. The same experience I have had likewise with patients that had their eye-muscles cut, often repeatedly, and who came to me for the reason that more operative interference had been declared necessary.

Furthermore, I have to add that the use of the weaker cylindrical lenses need not always be a permanent one, that they can be dispensed with after the tone of the ciliary muscle has been restored; and especially that it will not always be necessary to wear such glasses constantly, that is, for near and far objects; but that the eyes should never be used without them for near work until all the asthenopic symptoms have disappeared.

140 Madison Avenue.

Cæsarean Section should always take the place of embryotomy on the living fœtus, according to many modern gynecologists.

TREATMENT OF THE VARIOUS FORMS OF PULMONARY CONSUMPTION BY INOCULATION WITH VACCINE LYMPH.[1]

By J. HILGARD TYNDALE, M.D.,

NEW YORK.

A COMBINATION of pathological processes, which, alone or combined, lead up to a more or less active destruction of lung-tissue, and finally of life itself, is known to us under the comprehensive name of pulmonary consumption. These processes consist of: 1. The proliferation and subsequent contraction of connective tissue, met with in the lungs in the form of chronic peribronchitis with emphysema, a fibroid process, otherwise known as chronic interstitial pneumonia and as cirrhosis of lung-tissue; in the pleura by chronic adhesions leading to mechanical hindrance of the respiration and its consequences. Among the causes of these adhesive and shrinking tendencies the rheumatic diathesis plays a most important part. 2. The accumulation of mucus, pus, and cast-off epithelium in the bronchioli, followed by their incapsulation in greater or lesser foci—so called cheesy infiltration. Imperfect incapsulation of these products, aided by a more than mere temporary disturbance of the general nutrition, leads up to that most active of all destructive processes, namely: 3. The invasion of the tubercular bacillus. Really active destruction begins with the advent, proliferation, and dissemination of the bacillus. No other agency does lead to active destruction, a rapid downward course being due entirely to the local devastation or through a more general infection by the tubercle bacillus. Even in that most slowly progressive form of lung trouble, the connective-tissue processes, a sudden and rapid finale is precipitated by invasion of the bacillus.

We now come to points in physical diagnosis. No matter what line of therapeutics may be adopted, the main point is, and ever will be, a correct diagnosis of the existing condition. I could readily write a whole chapter on this question alone, but have already endeavored to do so in my paper, "A Plea for Physical Diagnosis."[2] To be skilful in physical diagnosis you must be able to size up each individual case in its totality. This includes the anatomical sufficiency and physiological expansive capacity of the thorax and the rapidity and rhythm of the heart's action. The secret of diagnosis lies in a discriminating comparison between the local and general condition of the patient. In gauging the local condition it is our duty to find out to what extent the lung territory has been permanently encroached upon, either by excavation or shrinkage; the extent of mechanical hindrance to respiration on account of fixedness of the bony thorax or pleural adhesions on the one hand, or defects in the upper air-passages—nose, pharynx, larynx—on the other, or, to reverse the above statement, we must find out if there is enough lung-substance left to carry on a proper oxygenation of the blood.

In gauging the general condition, the presence and the immediate or remote danger of a wholesale bacillus invasion is the most important point. The fat and blood formation of the patient next claims attention, together with his ability to digest food.

Having a clear picture of the local destructive process, as well as the impairment of the general nutrition, treatment should be begun in accordance to which of the two predominates as a destructive element. For, as we all know, there may be, roughly speaking, four kinds of cases:

1. Cases in which the general condition is good and the local destruction incipient, strictly localized, and just beginning to be active.

2. Cases in which the general condition is below par and the local incipient as above. These cases are very common and too frequently made light of.

3. Cases in which the constitutional impairment is grave and local destruction somewhat advanced and disposed to be active.

4. Cases in which the local lesion is quite extensive, but not active (dry cavities and shrunken infiltrations), and the general condition reasonably good.

Let this maxim be a guide: Each case is a law unto itself. You must form for yourself an exact mental picture of the individual case before you; not of the name of the disease, but of the condition. I quote from my late friend, Dr. Buren, of Philadelphia: "Bear in mind that auscultation is a study based on the comparative examination of the two sides of the chest in each individual case; since the quality and pitch of each person's respiratory murmur is a law unto itself." The great trouble is that the mathematicians in medicine speak of many-sided facts as if they were figures in arithmetic. As I said before, every case is a law unto itself, more especially as far as therapeutics are concerned.

Again, the presence of fine crackling or other moist râles merely indicates associated bronchial catarrh (chronic phthisis). Localization and persistence in connection with physical signs alone stamps their importance.

Another much misunderstood auscultatory sound is tubular breathing, notably at the apex. If percussion does not reveal more or less decided dulness at these points, our attention should at once be directed to mechanical hindrances to respiration in the shape of pleuritic adhesions. The importance of binding down of lung-tissue by interpleural plastic exudation has been dwelt upon by Dr. James R. Leaming, of this city, in a number of monographs. Dr. Leaming has shown that hindrance to respiration, to the entrance of air into some section of vesicular lung structure, are of the first importance, and not to be at all times looked upon as a mere accompanying lesion of an advancing lung process. No one can claim to be a physical diagnostician who will not, before entering into local details of auscultation, determine whether the case be: First, one of condensation of lung-tissue, either by a filling up process (cheesy infiltration), or of compression by connective tissue, or of both elements combined; second, one of mechanical hindrance to vesicular respiration by pleuritic adhesions, notably along the lower border of the lung, third, the combination of both of the above, when it becomes a matter of judgment whether the lung should be freed from its binding element first, or treatment of the general condition entered upon at once, or both therapeutical measures be combined.

Right here I wish to draw attention to one of the most formidable combinations of the infiltrating process with the binding down by pleuritic adhesions. I refer to cases in which the patient usually is in a very fair general condition, but where auscultation reveals what is known as "leathery creaking" along the inner edge and over the centre of the scapula, notably the right one. Not only are the adhesions in such cases firm and unyielding, but are associated with tubercular infiltration below them and frequently the immediate cause of hæmoptysis. Here is a field for some one to find a solvent for this dense connective tissue process, which by firm compression leads to condensation of vesicular lung structure and the formation of tubercular foci.

Let me now present my method. It consists of:

I. Exact and localized diagnosis. No case of pure connective-tissue proliferation, nor of general or localized cirrhosis of the lung-tissue—in other words, peribronchitis; nor case of pure mechanical disturbances of respiration caused by the binding down of lung-tissue by pleuritic adhesions; nor such cases in which diffused dry sibilant râles, heard all over the chest, point distinctly to obstruction in the upper air-passages (notably the nose), a mistake in diagnosis of every-day occurrence.

[1] Read before the New York County Medical Association, March 16, 1891. Followed by presentation of nine cases.

[2] Boston Medical and Surgical Journal, December, 1890.

The cases to be selected for inoculation are more or less active cavities and infiltrations with suppurative expectoration, with or without the presence of the bacillus, coupled to a not hopelessly impaired general nutrition.

II. The substance used for inoculation is the pure vaccine lymph obtained from the cow. This comes in capillary tubes containing about two drops. As a solvent I use simply fifteen drops of distilled water, to which is added one drop of pure glycerine. The fluid is injected subcutaneously near the seat of trouble. An ordinary hypodermic syringe is used and afterward cleansed by hot water and absolute alcohol. One capillary tube is used for one injection. At the third and fourth injection I have frequently used two tubes. Once in from six to eight days is sufficient. When the bacilli have disappeared, and the expectoration is sparse and of a mucous character, I inject once in two, three, or four weeks. No active reaction follows the injection. The temperature rises from one to two degrees in from eight to twenty hours after the injection and slight frontal headache is experienced. No abscesses form at the seat of injection.

As we all know, the actual losses from the body, if I may be permitted to call them so, to the consumptive patient may be summed up as follows:

1. Fever—a high temperature.
2. Expectoration—important as to its quality and quantity.
3. Night-sweats.
4. Loss of appetite.
5. Loss of muscular strength.
6. Diarrhœa.
7. Cough—as a peripheral irritation and consequent loss of sleep.
8. Feebleness and rapidity of the heart's action, leading to gradual exhaustion of the heart's muscle.
9. Fluor albus in women.

All of these manifestations are favorably influenced by the inoculation, some at once, others more gradually. Right here let me urge upon you the importance of persisting in the treatment. Even if the results are small in the beginning, a point will quite suddenly be reached at which the scale turns in favor of recovery.

III. Blood and fat formation. This line of treatment should be inaugurated at the earliest possible moment.

IV. Lung gymnastics. They consist of five deep inspirations every twenty minutes throughout the day.

V. The removal of obstructions or of causes of irritation in the upper air-passages. This should be done as soon as the patient is beginning to pick up. I know of nothing in diagnosis and therapeutics of lung diseases so often and shamefully neglected as this attention to the upper air-passages.

So far the remedy and the method. Before presenting my cases, let me say one word regarding the present advanced stand-point in our treatment of pulmonary consumption. Let all symptomatic treatment be abolished, except in case of great urgency for temporary relief. All supporting treatment, diet, cod liver oil, iron, malt, arsenic, corrosive sublimate, and the hypophosphites, have my endorsement, provided only they are not indiscriminately prescribed, but made to fit the individual case.

I desire to lay particular stress upon one point: We are now reasonably successful in treating connective tissue processes, equally so in the clearing up of cheesy infiltrations, even in which this clearing up does not result in a restitutio ad integram, but in leaving us in the presence of one or more cavities. When we come to deal with the presence of the bacillus, the question is whether these invaders are as yet localized—confined to their original habitation in an infiltration—or diffused; in other words, whether they have gone on a wholesale emigration throughout the lung substance. And right here is the present limit of our therapeutical possibilities. We may successfully eliminate local tuberculosis, but thus far the line is drawn at general dissemination of bacilli throughout the lung, usually manifested by a general bronchiolitis

It is evident to my mind that in the inoculation of animal virus, or intensely poisonous chemical compounds in very minute doses, we are now on the right track. We now have Koch's tuberculin, Liebreich's cantharidate of potash, Dr. J. Blake White's chloride of gold and manganese, and the bovine vaccine virus. Hypodermic injection appears to be the accepted method of introduction of these remedies. This is not the time to speak of their action—whether they kill bacilli, deprive them of their nutritive ground by more or less active serous exudation and casting-off of necrosed tissue, or whether they act as cell-supporters; or, again, by substituting one virus for another, thereby giving the system time to recuperate. For the present these are idle speculations. My own belief is that more than one animal and chemical virus will be found to accomplish the same object and that the secret of the whole matter lies in a correct diagnosis and the adaptation of the remedy to the individual case. Let exact mathematics in therapeutics be abolished.

LINEAR CRANIOTOMY FOR DEFECTIVE MENTAL DEVELOPMENT.

By WILLIAM H. MORRISON, M.D.,
PHILADELPHIA, PA.

When a new procedure is suggested for the relief of any affection, it is desirable that all cases subjected to it should be placed on record, in order that its advantages and disadvantages may be learned and its limitations speedily fixed. It is with this thought in view that the subjoined case is reported.

August 30, 1888, I delivered Mrs. L——, aged eighteen years, of her first child. The presentation was occipito-posterior, the occiput rotating into the hollow of the sacrum. Delivery was accomplished with the forceps after moderately prolonged effort. The child was a large male and had apparently suffered no harm. There was no depression of the skull or other sign of injurious compression. Two days later, however, a spot of sloughing skin appeared, just posterior to the angular process of the left frontal bone, leaving an ulcer one inch in diameter, which after a time cicatrized. The child developed physically fairly well, but it was observed as he grew older that he was not as bright as other children. He did not try to talk, nor did he make any attempt to stand or walk. He could not comprehend what was said to him.

In reference to family history it may be said that the father is twenty-three years of age, temperate and healthy mentally and physically. The same is true of the mother. On neither the paternal nor the maternal side is there any known tendency to mental disease or deficiency. There have been two children born since the birth of the subject of this paper. One is now eighteen months of age and perfectly normal in all respects, is bright, talks and runs around; the other is three months of age and its mental condition is apparently normal.

November 29, 1890, Dr. W. W. Keen published[1] the report of his first case of "Craniectomy for Microcephalus," giving an abstract of the cases of Lannelongue. I at once suggested the operation to the parents of this child, calling attention to the possibility of improvement and explaining the dangers of the procedure. The operation was accepted, but its performance postponed on account of the fact that the mother was nearing the end of her third pregnancy and it was thought advisable to wait until this was completed. The parents were urged in the meantime to try to teach the child to walk and to talk. During the next four months the child was under constant observation and every effort was made to improve its condition, but no effect could be observed.

The condition of the child at the time of the operation was as follows: M. L——, male, aged two years and five months; height, 32 inches; length of right leg, 15⅜ inches; length of left leg, 15⅝ inches, a difference of ⅛ of an inch;

[1] Medical News.

circumference at middle of thighs, 8½ inches. The measurements of the head were—occipito-frontal circumference, 18½ inches; semi-circumferences from one external auditory meatus to the other, 12 inches; antero-posterior diameter, 6½ inches; bi-parietal diameter, 4¾ inches; bi-frontal diameter, 3¾ inches.

He is able to sit alone, but cannot stand. He moves from one place to another by sliding on his buttocks. There is some contraction of the gastrocnemii muscles, so that when he is supported on his feet the body is thrown backward. The grasp of the two hands is equal and strong. The right patellar reflex seems absent, the left is normal. There is no apparent paresis or paralysis of the muscles of the legs. He is unable to talk. He can utter a few words. "Bert," "baby," "six," and "seven" is the extent of his vocabulary, and it is seldom that he can be induced to say even these. He cannot understand what is said to him. His only means of indicating that he wants something is by crying, and it is only by offering him various articles that it can be determined what he desires. His attention can be gained with difficulty and when gained, can be held but for a moment. He does not show that he understands when his name is called. Almost every day he has, without apparent cause, spells of crying without tears, which will continue for two or three hours. When pleased he will show it by a broad, idiotic smile. He eats fairly well and is well nourished. There is no incontinence of bladder or bowels.

The operation was performed April 17, 1891, with the assistance of Dr. H. A. P. Neel and Dr. E. E. Keiser. Ether was administered and the head shaved and then washed with soap and water followed by ether and bichloride of mercury (1 to 2.000) solution; antiseptic precautions were practised throughout the operation. An incision was made through the scalp, beginning at the line of the hair, two inches above the superior edge of the left orbit, and extending backward eight inches parallel with the median line, and three-fourths of an inch distant from it. Bleeding was controlled by hæmostatic forceps. During the early part of the operation a rubber tube was placed around the head to prevent bleeding, but it was found unnecessary and was laid aside. A one-half inch trephine was applied at the anterior angle of the wound, its centre being three-fourths of an inch from the median line, being so placed that the section in the bone would not correspond with the incision in the scalp. The button of bone removed was one-sixteenth of an inch in thickness. With the rongeur forceps, as modified by Dr. W. W. Keen, a strip of the skull three-eighths of an inch wide was removed, beginning at the trephine opening and extending backward seven inches, parallel with the median line and one-half inch distant from it. The posterior extremity of the bone section was one inch anterior to the extremity of the skin incision. The dura mater appeared healthy and was not markedly adherent. Bleeding from the bone stopped spontaneously, and no ligatures were required for the scalp vessels. The wound was thoroughly cleansed and united by numerous silk sutures. A few strands of catgut were placed at each extremity of the wound for drainage and a moist bichloride dressing applied.

During the next few hours vomiting occurred and was frequently repeated. There was considerable restlessness through the night and the child kept up a constant kicking movement. Fluid extract of ergot and camphorated tincture of opium were given in small doses, frequently repeated, but with little effect. The kicking movement continued during the next day (April 18th), and bromide of potassium was substituted for the ergot and opium. The temperature now began to rise, so that by evening it had reached 103° F. There was no vomiting and no apparent pain. Calomel was given to open the bowels, and three grains of antipyrine were given at 7 P.M., and the dose repeated at 10 P.M.

The following day (April 19th), the temperature in the morning was 99° F., and he had slept well during the night. His father stated that on being asked if his medicine were good, the child had uttered an emphatic "no," a word that he had never been heard to utter. During the day he rested well, but by evening the temperature had reached 101.5° F. The dressing was now removed for the first time, and it was found that the incision had united by first intention throughout its extent, with the exception of the points at which the catgut emerged. This had, however, failed to act as a drain, and the scalp over the section in the skull was bulging. The catgut was removed and there was a free discharge of serum, with some pus, from the posterior opening. A short rubber drainage-tube was introduced, and as the incision had been extended over the sound bone, its inner end did not come in contact with the dura. The wound was redressed with iodoform and bichloride gauze. It is probable that the kicking movements noted above were due to irritation of the leg-centres caused by the presence of the effusion. From this time, the course was uneventful, the discharge rapidly diminished, union became firm and by May 1st, two weeks after the operation, the wound was healed.

Signs of improvement in the mental condition were noted within a week after the operation, principally in the fact that his attention could readily be gained and held. When spoken to he would look toward the speaker and follow him with his eyes. The father's statement that the boy had said "no," a word he had never been heard to use, less than two days after the operation, has been noted. At the time this was considered rather as an effect of the imagination on the part of the father, but as a few days later the child again used the word several times and has continued to do so, the observation was probably correct. In the course of two or three weeks he was able to indicate food or drink by pointing toward the desired article. He soon added "yes," "stop," and some other words to his vocabulary. He would stand for a short time if placed by a chair, but seemed to fear that he might fall.

June 7th.—A careful examination of the child shows no apparent alteration in the measurements of the head. Since the operation there has been a continuous, gratifying improvement in the mental condition. The facial expression is much more intelligent. He notices and takes an interest in what is going on around him. He looks up when called by name. He can walk across the room when steadied by the hands. He will stand at a chair for a long time and for a few seconds has stood unsupported. The nutrition of the lower extremities has improved decidedly, but there is still slight contraction of the gastrocnemii. He makes constant efforts to talk and is gaining new words. When charged with doing something that he should not do, he says "I didn't;" when teased, will cry "Stop!" When asked where certain members of the family are, he will look toward the one indicated. He does not have the unmeaning crying spells to which he had been subject, nor does he roll the head from side to side as he did before the operation.

Until the suggestion of Lannelongue, about a year ago, the only hope for these unfortunate feeble-minded children lay in education, a measure not attended with the most satisfactory results. It does not seem logical to suppose that this procedure will benefit a large proportion of these cases, for in many there is probably more than a relative disproportion between the development of the brain and its bony covering; but even if a small number be reclaimed from utter idiocy and permitted even a moderate intellectual development, it is so much gained, and would justify a procedure attended with much greater risk to life than is linear craniotomy. The case now reported makes the eighth to be placed on record in this country. Of these, two have died shortly after operation, and one was reported so soon after the operation that the presence or absence of improvement could not be determined. In the remaining five, as well as in the

two cases reported by Lannelongue,[1] there has been a definite improvement observed. The cases so far operated upon have, however, been too few, and the time that has elapsed since operation, too short to enable any definite conclusions to be presented; but the fact that there has been decided improvement immediately following the operation clearly shows the relation of effect to cause, and warrants a continuance of the operation in these otherwise unpromising cases.

It is rare that any operation suggested for the relief of a definite affection limits its application to that condition. So it will probably prove with this operation of linear craniotomy. This thought is suggested by a case now under observation, that of a boy, aged ten, with a rather small head, and a mental development below the average, who, for several years, has been the subject of constant attacks of petit mal, varying in number from ten to twenty daily. With these there are occasional severe epileptic seizures at intervals of two or three weeks to as many months. In some of the major attacks it has been noted that the right side of the face and right arm have been distinctly more involved than the other parts of the body. There is no traumatic history, and no evidence of scar on the shaven scalp. In this case the proper course seems to be to make an exploratory operation and examine the region of the face and arm-centres for the right side, and failing to find there any explanation of the epilepsy, to do a linear craniotomy. Certainly it seems logical to suppose that if a certain disproportion between the size of the skull and the brain is sufficient to hold the functions of that organ in abeyance, a slighter disproportion might give rise to irritation of the brain, placing it in a condition of unstable equilibrium, so that the slightest cause would be sufficient to induce motor and other phenomena.

THE REPORT OF FOUR CASES OF PENETRATING GUNSHOT WOUND, INVOLVING THE CRANIAL, PLEURAL, AND PERITONEAL CAVITIES.[2]

By THOMAS H. MANLEY, M.D.,

VISITING SURGEON TO HARLEM HOSPITAL, NEW YORK.

As the occurrence of wounds inflicted by fire-arms in civil life is comparatively rare, and as each of these four cases in several respects possessed special features of noteworthy importance, it is assumed that a record of them, with a few comments on gunshot wounds which open into hollow viscera, will not be without some slight interest.

Three of the cases were admitted into Harlem Hospital during one week. No others had been seen by me, of this description, in my service there, for more than a year previously. The first was brought in November 22, 1890, and the third, November 29, 1890. The fourth was admitted September 14, 1889.

Case I.—In the evening of November 22, 1890, M. C—— , a young, healthy, vigorous woman, aged eighteen, was accidentally shot by her brother, who was handling a revolver when a cartridge exploded. Immediately after being wounded she fell to the floor bleeding from the head. In a few moments she recovered consciousness, when an ambulance was called and she was taken to the hospital. At the time when I saw her, one hour after the accident, she was sitting up in bed and was suffering none whatever from shock.

On examination I found that the missile had entered two inches external to the outer canthus of the right eye, just above the zygoma, had passed through the radiating fibres of the temporal muscle and was impacted in the shattered fragments of the squamous plate of the temporal bone, which it had penetrated. A free, deep, crucial incision was now made, dividing the terminal branches of the temporal artery and exposing the surface of the bone. The bullet was found lying on its long axis against the fragments of bone immediately beneath it. With a bullet-forceps it was easily dislodged. Now all the small pieces of depressed bone were removed, when we came on to the bare dura mater, which showed no signs of having been lacerated. After all loose, detached fragments of bone, and the torn, soft tissues were entirely cleared away, the cavity of the wound was irrigated with mercuric chloride solution, and the wound was dressed without the use of sutures, for the purpose of securing a free vent for any tainted or contaminated secretions, and besides, to secure union by granulation.

The day following she felt so well that she was desirous of leaving the bed. She had no constitutional disturbance of any description, had slept all night, and had a good appetite. There was no headache nor cerebral symptom of any description whatever.

The second day in hospital was uneventful, so that a

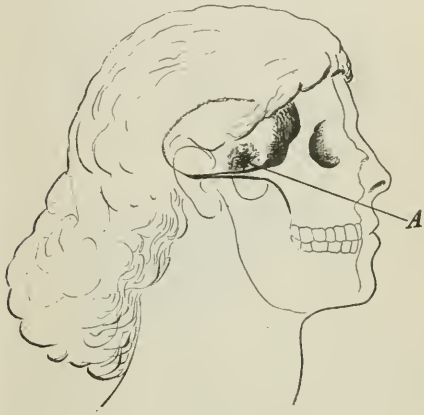

Fig. 1.

change of the dressings was decided unnecessary. She said except for the soreness over the wound she felt perfectly well, and was anxious to go home.

At about noon on the third day she commenced to complain of pain in the head and bodily weakness. At this time her temperature was 100½° F., and her pulse 115 per minute. During the forenoon she had vomited twice.

At two o'clock in the afternoon her wound was dressed. She would not get on the stretcher, but insisted on walking into the operating-room unaided. The wound looked healthy, was free from pus, and was closing in. There seemed no abnormal tension on the dura mater from beneath. She had returned to her bed but a short time when the nurse noticed that she was breathing heavily and was unconscious. Three hours later, five hours after walking out of the ward, she sank into a deep coma and died.

Post-mortem Examination.—Twelve hours after death the cranium was opened. The pia mater and arachnoid membranes were of normal consistence, free from any apparent pathological changes, except over the traumatized area. Here there were well-marked indications of incipient meningitis for a distance of more than an inch and a half from the circumference of the aperture through the skull.

Beneath that part of the dura mater which had been depressed by the missile there was a small blood-clot embedded in a mass of softened, disintegrated brain substance. There was some slight engorgement of the vessels in the hemispheres, with minute extravasations of blood into the convolution bordering on the fissure of Rolando. In other respects the brain was healthy.

[2] Read before the Section on Surgery, New York Academy of Medicine, May 11, 1891.

Case II.—Mrs. L——, eighteen years of age, native of the United States, was admitted into the Harlem Hospital on the evening of December 1st, suffering from a self-inflicted pistol-shot wound of the left lung.

While standing on the platform of one of our elevated railroad stations she suddenly unbuttoned her cloak, throwing it widely open, drew a revolver, aimed at her heart, and fired. Immediately after an ambulance was

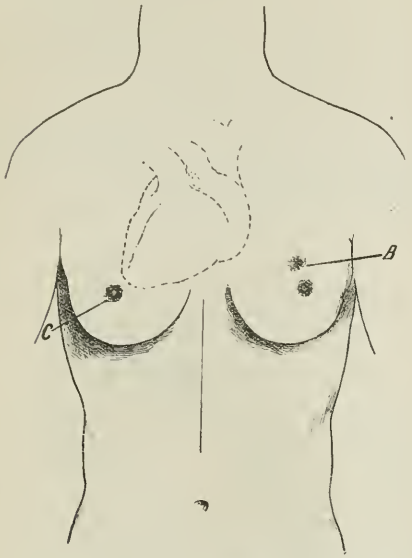

Fig. 2.—Anterior View. *B*, Aperture of entrance; *C*, apex-beat on right side.

telephoned for, and on its arrival the wound was temporarily dressed and stimulants were administered.

When she was seen by me, two hours after the shooting, she was suffering from collapse, and judging from the position and direction of the wound, it was assumed that some one of the large blood-trunks lying in the path of the missile was wounded, and that fatal internal hemorrhage must shortly terminate life. The ball entered one and one-half inch above, and slightly to the inner side of, the left nipple, emerging two inches to the inner side of the internal border of the scapula, beneath its spine, lying under the skin posteriorly. It was readily removed by a small incision. The lips of the wound of entrance were slightly everted, charred, and discolored by burnt powder. The wound was not probed, but was slightly dilated and cleansed of all foreign material accessible.

From her anæmic condition and the state of the lung, as revealed by physical examination, it was clear that there had been an enormous escape of blood into the pleural cavity. After dressings were applied she was placed in the recumbent position, iced-water towels applied to the left side of the thorax, and cold drinks given. There was but moderate oozing at any time from the wounds of entrance and exit, and there was no hæmoptysis. Antiseptic dressings were applied, and one grain of opium was administered.

On December 2d the temperature was 101.8° F.; pulse, 120; respirations, 30. On this date the dressings were reapplied. At this time there was no pleuritic pain; no bronchitis. On inspecting the thorax it was seen that there was no lung expansion on the left side. On the right side, however, it was evident, from the manner in which the shoulder and scapula were raised with each inspiration, that the lung had greatly increased in function, in order to compensate for the pulmonary inaction on the wounded side. On percussion the entire pulmonary area on the left side, except in the subclavicular space and over the spine of the scapula, posteriorly, was destitute of resonance. In carrying the ear over the region of the heart the usual normal sounds were wholly absent; nor was any impulse apparent to the touch. Over to the right side, however, about three inches from the border of the sternum, near the chondrocostal articulations of the fourth and fifth ribs, cardiac movement could be distinctly seen, and the apex-throb felt with the finger.

My first impression was that we had a clear case of congenital transposition of the heart; for it seemed scarcely possible that sufficient sanguineous effusion could escape into the pleura to crowd the heart over the anterior mediastinum without inducing fatal anæmia. But the patient herself said that she always previously felt the heart's impulse on the left side, and that she aimed the weapon with a view of penetrating that organ when she fired.

In order to clear up any doubt on the matter, I invited Dr. John G. Truax, Visiting Physician to the Harlem Hospital, in to see the case. After a most thorough physical examination he informed me that the displacement was mechanical and recent, as he had determined by many tests. On puncturing the left pleura at different points with the exploratory needle, he withdrew a bloody liquid.

Up to the fifth day of admission the case pursued a most favorable course, the temperature not yet reaching higher than 99.5° F. The apertures of entrance and exit were carefully dressed, and manifested a tendency to rapidly fill in with granulations. Now the question arose in my mind whether it was in consonance with rational treatment to close in those apertures, or purposely prevent union of them until the effused blood was absorbed and all danger of septic inflammation was past.

It might be argued that by sealing in those vents all possible danger of future contamination through the wounds would be impossible. Yes; but the pulmonary

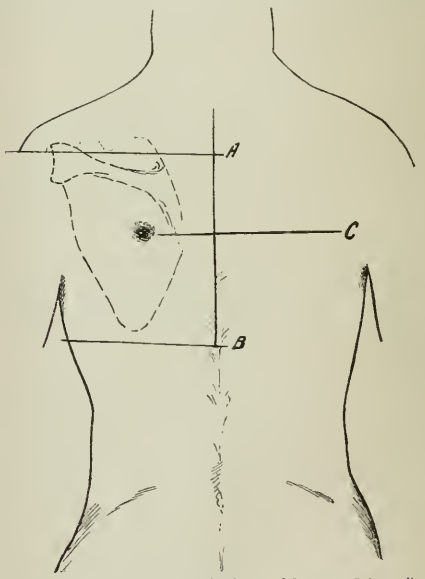

Fig. 3.—Posterior View. *A*, Upper limit of area of flatness; *B*, lower limit; *C*, aperture of exit.

parenchyma was torn through by the missile, large vessels divided, and the smaller bronchial tubes opened, so that by way of the air-passages a means of infection was constantly open, and hence it could be only a matter of time when putrid changes would develop in the wound, in consequence of the access of pathogenic germs through

the respiratory tract. Further, in the event of pus formation, unless a free vent were given to it and the infected sanguineous mass within the pleura, fatal results must ensue. It seemed to me that in these cases of gunshot or stab wounds of the lung, inasmuch as we can by no means within our power prevent infection through the air-passages, provision should be always taken to provide for free irrigation and drainage when purulent changes should make their appearance.

On the fifth day the woman had a violent chill, quickly followed by lancinating pains in her left side, great prostration, and a rise of temperature to 104° F., with a pulse of 126. She passed a very restless night, with no sleep, but great thirst.

At noon on the 6th her dressings were changed. At this time a thick silver probe was introduced into the anterior aperture. This was immediately followed by a large sanguino-purulent discharge, which came away in considerable quantities. The irrigating tube was now inserted, and the pus cavity thoroughly drenched by a mercuric solution. Now a drainage-tube was inserted, and she was turned on her left side and placed in the position that best favored drainage by gravitation. Her symptoms immediately improved, so that by the next day the temperature was again normal. The anterior perforation continued to discharge freely a foul secretion until the sixteenth day, when it commenced to notably diminish, and by the end of the third week it had wholly ceased.

This open, dependent, thoracic drainage saved the young woman's life. In wounds of this description bronchial infection is inevitable. One might assume that the tainted material arising from microbic invasion must needs find a free vent by way of the trachea; but a careful observation of the course which the gases take as they enter the minute bronchi and pulmonary alveoli, will at once explain this singular phenomenon in pneumo dynamics, by which the inward wave of air must make a circuit on entrance in a centrifugal direction before it returns.

We have many clinical illustrations of this in traumatisms which involve the periphery of the organ when the air-vesicles give way. The air as it descends into the lung, immediately escaping by the same channel in which it entered, is drawn downward into the lower lobes and forced into the resisting connective tissue, so that we have an emphysematous condition present of varying extent.

When our patient left the hospital, four weeks after admission, her lung had wholly regained its normal power, and she was fully restored to her former health.

Case III. *Penetrating Gunshot Wound of the Pleura, Lung, Peritoneum, Liver, and Stomach.*—Peter S——, aged twenty two; single. This patient, as the preceding, made a suicidal attempt on his life, employing a 32-calibre Smith & Wesson revolver. He shot himself at five o'clock on the evening of November 27th, two hours after eating a hearty dinner, into which fowl largely entered. When he fired he was in his shirt-sleeves, and aimed directly at the heart. I saw him two hours later in the hospital. At this time he was of a deathly pallor, but the extremities were warm. His nose, eyes, and ears were of a marble whiteness. The pupils were widely dilated, and the sclerotica was of an unnatural lustre. The body was bedewed by a copious perspiration. Breathing was shallow, accompanied by frequent sighs. The pulse was thready, and beat 140 to the minute. He lay in a listless state, and only spoke when questioned. He was warm, and when roused he articulated with clearness and energy. From the time he entered the hospital he incessantly vomited, the ejecta consisting mainly of blood mixed with mucus, partly digested food, and iced water, which was given him to slake his unquenchable thirst. He said that he felt very weak, but had no pain except over the region of the left kidney. Here, he was quite positive, the ball was lodged, for he complained of a sharp burning pain in this situation when he moved the body, coughed, or vomited.

Exteriorly there was no unusual fulness at the point of pain. On withdrawing some urine with the catheter there was no trace of blood to be found in it.

The location of the wound in the wall of the thorax was just two and one-half inches below the left nipple, and on a perpendicular line with it. The missile entered through the fifth intercostal space, close to the superior border and near the centre of the sixth costal cartilage. The aperture of entrance was large, with circular, ragged, blackened borders from which minute particles of powder were picked with fibres of the clothing, which was perforated. It bled but little. After carefully cleansing the orifice of the wound a bullet probe was introduced. On moderate force it entered for a

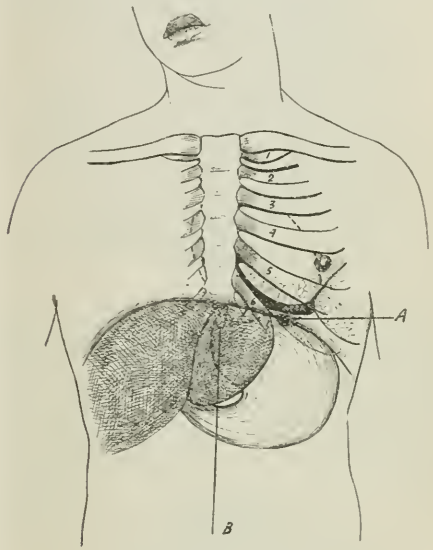

Fig. 4.—Anterior View. *A*, aperture of entrance; *B*, Abdominal incision.

depth of two and a-half inches, taking an outward, backward, and downward direction. When this was withdrawn I introduced my index-finger, as I supposed, directly into the pleural cavity, and imagined that I could distinctly feel the bare apex of the heart as it lengthened in each diastole. The thump against my finger was so forcible that with each impulse the whole hand was moved to and fro. This manipulation caused some slight hemorrhage externally. There was no emphysema. On applying the ear over the precordia, with each contraction of the heart a peculiar splashing sound was distinctly heard. The lower pulmonary area below the nipple line on this side was flat on percussion, nor could any respiratory murmur be heard on applying the ear.

Judging from the position and direction of the bullet track, in connection with other physical phenomena present, it was evident that the missile must have torn through a large blood-trunk, which was draining into the pleural cavity. The suspected vessel was the internal mammary artery, a vessel deeply lodged, and in this part of its course wholly inaccessible.

Were the pleura, lung, peritoneum, and stomach, penetrated?

Reasoning on theoretical premises, and calculating from anatomical landmarks, if the ball had passed onward, making a breach through the diaphragm, this enormous accumulation of fresh arterial blood should have gravitated downward through this vent and flooded the cavity of the peritoneum, but there was no physical evidence of hemorrhage within this sac. Nowhere was the abdomen

unduly distended, nor on careful percussion was any dulness or indication of displaced viscera to be elicited. Change of posture and pressure applied over the hypogastrium gave no proof whatever of a fluid accumulation. On the contrary, the abdomen was rather flat and tympanitic. But the man was raising blood copiously from the stomach, and it was incontestable that its walls could not have been pierced without the bullet engaging, in transit, the peritoneum and left lobe of the liver.

Now, if the bullet perforated the anterior wall of the stomach, had it lodged within its free cavity, so that it might be ejected through either orifice? Or did it, in its path, penetrate both walls, and fall into the peritoneal cavity; or, further, traversing on a direct horizontal line through the stomach, did it penetrate the shelving, posterior, arching crus of the diaphragm, and enter the pleural cavity again?

Unfortunately, notwithstanding what may be said to the contrary, we are not yet in possession of any device by which we are enabled to recognize or differentiate the various lesions within the peritoneum in cases of gunshot wounds. Hence, in the present instance, the most we could reasonably assume was that the parietal pleura and lung were opened, and that the vascular walls of the stomach were probably perforated.

About one thing there was no doubt, however, viz., that this man was suffering from an alarming hemorrhage, which must soon terminate mortally unless it ceased of itself or by the intervention of art.

Was surgical interference—an abdominal section—justifiable under the circumstances, assuming that nature's unaided efforts were not sufficient to subdue the hemorrhage? Senn, in his latest brochure on gunshot wounds of the abdomen,[1] lays it down as an axiom "that we must not open the abdomen for treatment of gunshot wounds above the umbilicus, unless we have proof of perforation or extensive hemorrhage into the peritoneal cavity."

Now in this case we had no proof of either, and events will show that we may have not a single but a double perforation of a viscus without any leakage whatever. The patient, having full possession of his faculties, gave me permission to do what I deemed most prudent or desirable.

As his case was one of suicide, and consequently, if it terminated fatally after incision I felt that I would not probably have to defend myself as a contributory agent, as might be the case under other circumstances; and besides, as I hoped to reach and secure the bleeding points within the abdomen, arrangements were speedily made for the epigastric incision. Having made ample provision for emergencies which might arise, and freely stimulated our patient, the exploratory operation was begun. The room was well lighted and heated, with every precaution against infection carefully observed. An incision was rapidly made, extending from the ensiform cartilage to the umbilicus. In coming down on the gastro-hepatic omentum it was divided and pushed aside. Now the left lobe of the liver, with the white, glistening, convex surface of the stomach came into view, and the peritoneal cavity was opened. But not a drop of blood could be seen, nor any other foreign substance. The fingers were carried over the free border of the left kidney; but nothing was amiss there, where he supposed the missile had lodged.

Having thus far discovered nothing except the perforation in the liver, I placed my hand flatwise against the interior wall of the stomach and gently pressed it backward, when all at once it was bespattered with blood, and with each inspiration there was a distinct, hissing, suction sound, similar to that which we hear when air enters the pleural cavity through an opening in the thoracic wall.

At this stage our difficulties commenced; as it will be observed that the opening into the stomach was immediately under the left lobe of the liver, about seven inches above its free border, and in contact with its posterior surface, above and behind the lower margin of the costochondral articulations of the sixth, seventh, and eighth ribs. Although the blood escaped in spurts from the wound in the wall of the stomach, the perforation could not be seen, owing to the position it occupied. However, by making gradual but firm traction in the perpendicular axis of the stomach, the perforation came into view, though it was situated so high up that with each expiration it was drawn up completely out of sight.

After firmly fixing two strong tenacula in the gastric walls, including everything except the mucosum, and putting the parts on the stretch, we were enabled to again bring the bleeding orifice into view. But even now the introduction of sutures into an organ in perpetual motion was almost impossible. By a quick movement, as the viscera descended with the ingress of air into the lungs, I was able to invert the edges of the opening and insert two interrupted Lambert sutures. Fearing the consequences which might follow such extreme tension as it was necessary to employ, we relaxed our grip three or four times in the course of suturing. After two deep sutures were inserted, a continued suture was carried over all. Now the hemorrhage completely ceased externally. Not finding any other perforations the peritoneal cavity was flushed with warm sterilized water, the omentum replaced, and the abdominal incision closed.

Our patient came out of anæsthesia well, though at one stage of the operation he was quite pulseless. He passed a very comfortable night, vomiting no more, but, early in the morning he had a large discharge of discolored blood-clots by the rectum.

The day following operation, in the morning, his temperature was 99° F.; pulse, 118; and respirations, 31. He was given bits of ice to eat through the day, and enemata of milk-punch were administered every two hours. Before evening on this day he had two more large motions, consisting of almost nothing but blood. It was evident that when the vomiting ceased the blood had taken a downward direction.

Through the night of November 29th—the second in hospital—he had six small passages of black, partly digested blood-clots. When I saw him on the morning of November 30th, at five o'clock, his condition was excellent. He was then taking champagne by the mouth with relish, and was retaining it. He said he felt "first-rate" and expected to get well. At this time, without disturbing him, I removed the drainage-tube and changed the dressing. His belly was then flat and soft, with entire freedom from tenderness. During the day he clamored for something to eat, and said he was very hungry. Small quantities of beef juice were given him now, and were well borne.

Monday morning, December 1st, his temperature was 102° F.; pulse, 130; respirations, 26. He passed a comfortable day. In the evening at two o'clock he was suddenly taken with a violent pain under the left shoulder-blade, and commenced to breathe with great distress. The temperature ran up to 105° F., and pulse to 140. With the onset of this sudden collapse, although his mental faculties were yet undimmed, he gave up all hope.

December 2d, in much the same condition. The pleuritic pain in the left side constantly tortured him, and local application of hot stupes and fomentations, with the free administration of opiates, seemed to make but little impression on it. The whole of the left side of the thorax was extremely sensitive to the touch, and on percussion flat and non-resonant. At this time respiration was maintained wholly by the right lung.

December 3d.—In the early morning his condition was more hopeful and he was taking nourishment freely. After midday, nevertheless, he began to grow weak, the pulse was thready and flickering, the extremities became cold At 12.45 A.M., December 4th, he died, on the eighth day after admission.

[1] Penetrating Gunshot Wounds of the Abdomen, Meeting of American Medical Association, Nashville, Tenn. May, 1890.

Post mortem Examination.—Twelve hours after death the body was opened. The thoracic and abdominal cavities were exposed by the scalpel, and their walls widely separated. It was found that the missile had taken a course directly backward and outward, and had pierced in transit the integuments, the intercostal muscles, the diaphragmatic branch of the internal mammary artery, the costal and pulmonary pleuræ, the lower lobe of the left lung—one and one-half inch from its free anterior border—the muscular crus of the diaphragm, the peritoneum, the left lobe of the liver, both walls of the stomach; again entering the peritoneal and the pleural cavities posteriorly, it passed completely through the lower lobe of the lung and embedded itself in the fibrous covering of the eighth rib, four and one half inches from the costo-spinal articulation. The left lung was found compressed into a small, shapeless mass at the apex of the pleural cavity. It was deeply congested, and on its serous surface was firmly adherent to the enormous blood-clot which compactly filled in the pleural cavity. This coagulum, by its pressure on the serous membrane, had evidently excited an adhesive pleurisy, for everywhere it could be peeled off in laminated layers, in which were mingled numerous flakes of coagulated lymph. The liquid elements of the effused blood had been resorbed, and the central portion showed evidence of disintegration preparatory to final assimilation. At the point of perforation of the bullet the lung was hepatized, and a small quantity of pus was found directly under the pulmonary pleura, about one inch from the free border of the lobe, through which the bullet traversed.

On opening the abdominal cavity it was found that the incision had not completely healed by first intention, but there was no trace of peritonitis nor effusion. The perforation through the liver had filled in with a granular material, which offered considerable resistance to the probe. The stomach was now wholly removed and distended with water. The sutured aperture was hermetically sealed, though there was a slight oozing through to the upper posterior wall of the stomach. By observing the direction from whence the fluid came we discovered the second perforation.

The first opening made by the bullet into the stomach was through its thick muscular coat, close to the œsophageal orifice; the posterior was one inch lower down, at a part uncovered by peritoneum. The organ was empty of aliment. All the organs of the body were normal, except those directly implicated in the wound.

Case IV. *Penetrating Gunshot Wound of the Lung and Stomach—Treated by the Expectant Method—Recovery.*—C. B——, male, aged thirty-nine, foreigner, married. Admitted into Harlem Hospital September 13, 1889, at 8 P.M. Previous history: Was shot through the right side in the Franco-Prussian war, the missile entering two inches forward of the anterior border of quadratus lumborum muscle, just above the crest of the ilium. The bullet is still in his body. He claimed that the present wound was accidental, having been caused by the discharge of a revolver while he was cleaning it — a 32-calibre weapon. The police, however, and others maintained that he attempted suicide. This view was strongly supported by later revelations, from the position and direction of the powder-burned perforation, and from the fact that, as in the two preceding cases, the heart was the objective point. Three hours after admission he was seen by me. At this time mortal symptoms were present. The radial pulse was intermittent and barely perceptible, the extremities were cold, and the whole body was bedewed with a copious perspiration. He was deathly pale; the nose, lips, and ears were of an ashy white. There was a distinct and constant spasmodic twitching of the muscles of the eyeballs and lips, and he was almost continuously dropping blood and foam from the mouth. He lay on his back, with half-closed eyelids, breathing by gasps and sighs.

On examining the body it was seen that he had shot himself, the bullet entering three inches below the left nipple, and a little more than one inch to the inner side of a line passing downward in a perpendicular direction from it, just below the apex of the heart, through the sixth intercostal space. From this point it took a backward direction and lodged posteriorly, shattering the shaft of the tenth rib five inches from the spinal articulation,

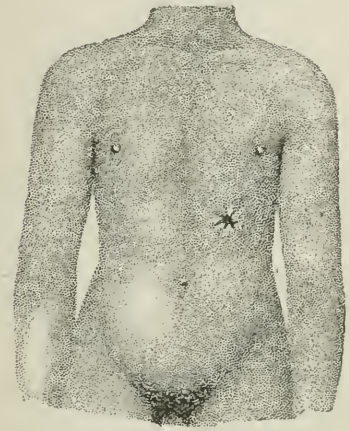

Fig. 5.—Anterior Aspect—Wound of Entrance.

and giving rise, by the emphysematous escape of the pulmonary gases and effused blood into the adjacent tissues, to a large, globular swelling under the integuments about the size of a billiard-ball. A simple antiseptic dressing was now applied, and measures resorted to with a view of securing prompt reaction, if possible. He was placed in hot blankets and warmed by the application of heated bottles of water placed in large numbers about him. Hypodermic injections of brandy and frequent stimulating

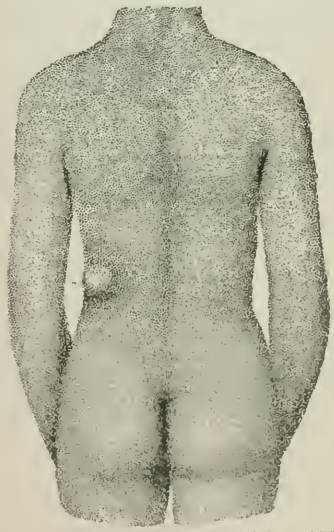

Fig. 6.—Posterior Aspect—Conical Protrusion of Shattered Rib.

enemata were administered. Internally he was given nothing but fragments of ice to slake his thirst, and two drops of laudanum every twenty minutes. He passed a very restless night, vomiting coagulated blood in large quantities, and complaining of severe pain in his left side.

September 14th, 10 A.M: Temperature, 98° F.; pulse, 130; respirations, 34. P.M.: Temperature, 99⅘° F.;

pulse, 80; respirations, 24. From this date until the 20th—four days—his general condition continued to improve. His side gave him considerable pain both night and day. On the evening of this date he had a chill, and the temperature rose to 101° F., and the pulse to 126. His breathing became suddenly labored and painful. On percussion it was evident that the left pleural cavity was the seat of a large sanguinolent effusion. He was now taken to the operating-room, and a free incision over the convexity of the fulness posteriorly was made. Through this the bullet, flattened and indented was removed, together with several small spiculæ of crushed rib; broken down blood-clots, and a considerable quantity of a sanguino purulent matter. A drainage-tube was introduced and the parts were thoroughly irrigated. From this time the pain diminished, coughing ceased, and steady improvement in his general condition was noticed. The effusion into the pleural cavity was rapidly resorbed.

On the seventh day after admission the aperture of entrance had closed in, and that of exit was well contracted.

On the 23d—ten days after the shooting—his friends came and took him home. He returned to the hospital once a week, for a month, until the incision in the back had healed. He made a perfect recovery, and has since been in excellent health.

It will be observed in this case that although the pulmonary parenchyma was perforated there was no hæmoptysis at any time, unless it was immediately after he was shot, when so much frothy material issued from his mouth.

This was the only one of the three cases of traumatic pulmonary lesion in which there was well marked emphysema. It is likewise noteworthy and important to observe that in this, as in the two preceding cases, no serious symptoms appeared until after the lacerated tissues had become infected by germ invasion through the air-passages; and that they vanished rapidly and completely as soon as a free vent was given to the pent up decomposing material within the pleural cavity.

In the case just cited was the stomach perforated? did the missile, in its path, make an opening through both of its walls? If so, are stomach wounds in the human being necessarily mortal when active surgical intervention is withheld?

With respect to the first query, considering the site of the initial orifice, the range which the bullet took, and the fact that the man had shortly before using the revolver eaten a hearty meal, the stomach could not possibly have escaped. Besides, the free and copious vomiting of blood after reaction was established more clearly emphasized the probability of this organ having been wounded.

It might be alleged that as there was no emesis of blood immediately on entrance to hospital, the walls of the stomach were not penetrated. But it should be remembered that after the shot was fired he at once became unconscious and fainted; that he was in profound collapse for several hours before the system regained its equilibrium and the vital powers their wonted energy.

Inasmuch as there was no evidence of hemorrhagic accumulation into the peritoneal cavity—which, as we supposed at that time must always be the case when the cavity of the stomach is opened by a ball—we were undecided as to diagnosis.

But Case III. definitely decides the fact that the stomach may be perforated through and through without the necessity of either the gastric contents or effused blood emptying in any quantity whatever into the peritoneal cavity. The importance of this fact cannot be overestimated when we are called on to deal with bullet wounds which involve the stomach.

When it is remembered that the stomach, whether distended or empty, always lies in close contact with the inferior surface of the diaphragm, along with the circumjacent viscera, we may more readily appreciate the manner in which free hemorrhage into the large lymph sac of the abdomen is prevented, the blood flowing into the lumen of the alimentary canal.

It can be scarcely doubted but at the instant of explosion of the cartridge in suicidal cases the respiratory act is for the moment in abeyance. The unfortunate takes a long inspiration, points the weapon, and fires. If the wound has not been immediately mortal, more or less shock follows; the heart's action is so feeble that should one at this stage open a small vessel no blood will escape.

During the interval of shock the thick muscular walls of the stomach, which are rich in abundant muscular fibre, the fasciculi of which fuse and interlace in every direction, have so contracted over the perforation that by the time the system has reacted, the gap is closed in.

Dr. J. H. Conway, of Eudora, Ga., recently reported the case of a man shot from behind, with a 38-calibre Smith & Wesson revolver, "the ball entering close to the spine, on the left side. After being shot he ran about two hundred yards, then became very sick and vomited

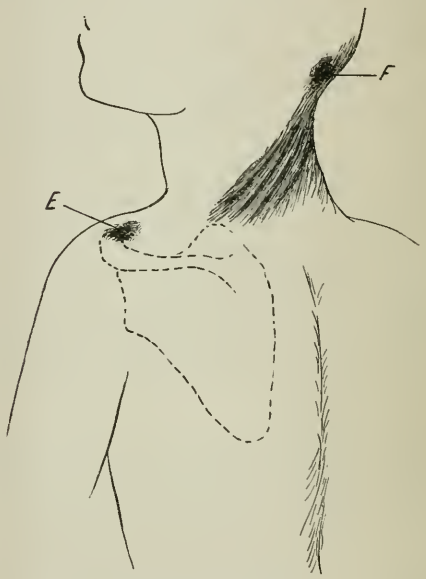

FIG. 7.—Penetrating Gunshot Wound of the Spinal Canal. *E*, aperture of entrance; *F*, aperture of exit.

freely of food and blood. He was brought home, a distance of about a mile from the spot where he was shot. About half an hour after he entered his house, while in bed, with his head hanging over its edge, he vomited the bullet, with a large quantity of clotted blood. Sixteen days after he was wounded food was freely given him, and he made a rapid recovery.[1]

Paul Berger, at the Congress of French Surgeons recently in session in Paris, reported two cases of penetrating gunshot wounds of the stomach, with rapid and perfect recoveries in both without intervention. He included in his article five other cases of penetrating wounds of the abdomen, occasioned by the knife and bullet. Those who were stabbed recovered without abdominal incision.

In three cases, in all of which the intestine was wounded, laparotomy was performed; two of these resulted fatally. He concludes his valuable contribution by saying that in penetrating gunshot wounds of the abdomen, with lesion of the intestine, abstention should be the rule when there are no indications of peritoneal infection, or when this follows a subacute course.[2]

[1] Dixie Doctor, March, 1891, p. 70.
[2] La Tribune Médicale, April 9, 1891.

In cases of gunshot wounds of the stomach, unless there be present well pronounced and positive evidence of free leakage of the stomach's contents and blood into the peritoneal cavity, abstinence from surgical intervention should be the rule. The perforation or aperture of entrance should not be probed nor explored, nor, in my judgment, should any violent means be resorted to for the purpose of attaining an accurate diagnosis. The hydrogen insufflation test seems to me particularly reprehensible in these cases. The passage of a large tube through mouth and pharynx into the œsophagus of a man in almost a moribund state is attended with difficulties better imagined than described. And assuming this manœuvre safe and simple, the stomach being already partly filled with blood or ingesta, must expand to make way for every cubic inch of gas injected, or else a cubic inch in volume of its fluid contents must be displaced. Where? Not in the direction of the œsophagus, for that is plugged by the tube. The displaced contents may pass downward through the pylorus. But supposing that they escape through the bullet wound in the gastric wall, or, as in the case of the young man on whom we performed laparotomy, there is a double perforation which deluges the peritoneal cavity with a grumous mass of partly digested food and blood? But the stomach may be empty, there are no solids or liquids in it. The relations of the parts have now, however, unhappily changed, and no gas appears at the outer aperture until the ventral cavity has been greatly distended, the diaphragm crowded upward and backward with great force against the heart and lungs, so that life may be imperilled by asphyxia, especially if this method is applied to the male sex. The possibility of explosion at the moment of ignition of the escaping gas is not to be overlooked.

Although facilities were at our command by which we could with ease and precision locate perforation, if the lesion were in the course of the lesser curvature of the stomach, in the left hypochondriac region, beneath and above the free borders of the sternal ends of the lower seven ribs, would we always be able to close in bullet perforation by surgical intervention? A considerable area of the surface of the stomach is wholly inoperable. This is attributable to the fixed, concealed arrangement of the superior expanded segment of the organ, which lies high up behind the left lobe of the liver, and its under surface is in immediate contact with the larger blood-trunks.

The application of sutures in any part of the walls of the stomach, either anteriorly or posteriorly, which are covered in by the liver above, is always attended with very great difficulty. Difficulties do not arise so much, however, from the stomach's concealed position as from the constant up and-down motion imparted to it by the diaphragm. Owing to this phenomenon steady fixation of the organ during delicate and tedious manipulations of it is an impossibility.

The treatment of small stab wounds or gunshot perforation of that portion of the stomach lying in the left hypochondriac region should then always be tentative, conservative, or palliative. A penetrating wound in this situation before it can reach the stomach must pierce the lower lobe of the left lung and the left lobe of the liver when the point of penetration is within five inches of the median line to the left. Hence we must bear in mind that even though the stomach were accessible for repair there would yet remain a double danger, first, from hemorrhage from the hepatic or pulmonary tissues, and second, from infection. But we may endeavor to keep the puncture through to the lung open by stuffing it with fine gauze and not permit it to close until all shreds or fibres of clothing, detritus of necrosed tissues, and infected material have drained away.

The alimentary canal, along with being the digestive tube of the body, may also be regarded as a sort of sacculated and convoluted ventilating funnel. It differs from any ordinary ventilator only in its arrangement, inasmuch as instead of the consumed, polluted gases escaping from above, it is here that the oxygenated supply enters unmixed, or in conjunction with the ingesta, and is thrown off, or exhaled as it were, below by the rectum.

The stomach demands a considerable supply of air as well as liquids in the work of oxidation and effecting chemical change in the food which enters it. Now, if when suddenly perforated it apply itself in such a manner against some contiguous part, by the action of the vacuum within the peritoneal cavity, then none of its gaseous elements will escape; nor will atmospheric air enter the peritoneum and diffuse itself in such a manner as to displace that provisional approximation supplied by the economy.

Accordingly no probing should be resorted to in those cases, but every precaution observed to secure rest. After the wound has been thoroughly cleansed and antiseptic dressings applied, a broad, smooth bandage must be applied for the purpose of taking the strain off the muscles and supporting the viscera.

Extreme quiet of mind and body are indispensable. The patient should be nourished by enemata. Opium in small doses in these cases is a sovereign remedy. By calming the mind and subduing pain the system is placed under the best possible influences to complete the reparative processes.

I have incorporated the first case here, that of gunshot wound of the skull, simply as one of the many cases which have come under my observation in which results and symptoms have borne almost no relation with the extent of local injury; and it goes a certain way toward disproving the modern theory of cerebral localization.

From the cases here reported with respect to penetrating wounds of the pulmonary parenchyma and of the stomach; from my previous experience and all that I have been able to gather from the experience of distinguished authorities, and from our present advanced knowledge of pathological processes dependent on septic invasion, it may be permissible to affirm that,

1st. In every case of penetrating gunshot wound of the lung the aperture of entrance should be carefully guarded against contamination until all foreign substances carried inward by the missile have been thrown off, and it should be kept well open till all danger of septic infection by way of the air passages is passed.

2d. Should purulent infection arise, the aperture of entrance must be freely widened in order to effect deep drainage and dislodge by irrigation infecting accumulation.

3d. Under ordinary circumstances penetrating wounds of the stomach must not be disturbed by active surgical intervention as their usual tendency is toward recovery.

4th. Owing to the concealed position of the convex cardiac segment of the stomach, behind and above the liver, a perforating wound through its walls in this situation is inaccessible and beyond the reach of safe manipulation.

Germany very Backward.—The largely signed petition, praying "That the study of medicine at German universities be thrown open to women, and that women duly qualified be allowed to practise the medical profession," was contemptuously dismissed in the German Reichstag. That the petition would be rejected was a foregone conclusion. But it might have been expected that the question—which is everywhere acknowledged to be a burning one—would have been seriously discussed. It seems, however, that this was thought quite unnecessary by the opponents. The arguments against the petition were of the familiar, well-worn description, more suitable to a provincial debating club than to the Parliament of the German Empire. "Women should keep house, and not meddle with science. Women who study are objectionable." This was the gist of the opponents' speeches; the discussion did not rise above this level, and the petition was quietly thrown out.—*British Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 18, 1891.

THE SIN OF DRUNKENNESS.

WE have heard a great deal about the disease of inebriety, and of how absurd and unscientific it is to consider an obstinate tendency to drunkenness a vice. It is interesting therefore to hear a declaration regarding the other side from Mr. Charles A. Bunting (*The Independent*, June 11, 1891). Mr. Bunting says:

"Drunkenness is not a disease; it is not hereditary, but a sin. This is shown by two thirds of all who come to our Home. One-half and more neither had intemperate parents nor grandparents. Association was the cause in two-thirds of all the cases we have had, showing conclusively that it is a habit acquired. In one thousand two hundred and ninety instances the habit was acquired after coming of age and leaving the domestic fireside. If drunkenness is hereditary why is it that in ninety-nine cases out of a hundred the boys catch the "disease" while the girls do not? A strong argument against the hereditary theory is a statement made to me by the Superintendent of the Home for Little Wanderers, in Boston. He says that out of five thousand seven hundred children, more than half of whom were boys, he could recall but one boy who had become a drunkard. When we consider that the great majority of these little waifs are the offspring of drinking parents, and, in many instances, the children of parents both of whom are common drunkards, does it not seem strange (if drunkenness is hereditary) that out of such a large number there is not more than one instance of its transmission shown in the nearest offspring, without having to await its development in the grandchild or the great-grandchild?

"Nothing but God can meet the needs of the drunkard. No medicine can eradicate the cravings of the victim of alcoholic beverages. It is not a disease, and Christ can and will destroy all desire for intoxicants, if the sufferer will apply to him for aid. Hundreds who have tried all other remedies and plans have found in our Home that the Great Physician can cure the sin-sick soul."

These views will no doubt meet strong opposition in many quarters; yet to a certain extent they are in harmony with common-sense and practical experience.

Many inebriates were undoubtedly made so by gradually increasing indulgence in alcoholic liquors. Their systems became disordered to such an extent that self-control was lost and a morbid craving produced. Powerful mental influences which stimulate the will and help one to self-control will often effect a cure of these cases. The cause is social or psychical; the cure is psychical; hence it is not unnatural that many persons should call drunkenness a moral disorder rather than a physical one.

THE NUMBER OF TUBERCLE BACILLI IN PHTHISICAL SPUTUM.

DR. E. H. F. NUTTALL, of Johns Hopkins University, has shown that phthisical patients expectorate from 250,000 to 4,000,000,000 bacilli in twenty-four hours. Taking the average of, we will say, 100,000,000 per day, the patient would expectorate 365,000,000,000 bacilli a year, and if he lives three years, the total number of micro organisms expectorated during his illness would be 1,095,000,000,000. Or multiply the year's annual out-put of 365,000,000,000 by 70,000, the number of cases of phthisis in this country, and we are confronted with the sanitary problem of destroying 75,000 times 365,000,000,000 microbes every year. These are rather discouraging figures, but it may be supposed that the vast majority of tubercle bacilli in the sputum die as the result of intercurrent disease or a pitiless environment.

THE BOOKS IN THE TALL TOWER.

THE library of the American Medical Association received the following important additions during the past year, viz., 45 periodicals, 24 reports of various kinds, 14 society transactions, 5 hospital reports, 16 dissertations and papers, and 8 college announcements.

The library, as we gather from the annual report, lies in one of the tall towers of the Smithsonian Institute, and the librarian complains that more room for it is needed. If last year's additions represent the general character of the library, we suggest its transferrence to the cellar, or its disposal in the interiors of the various manikin fishes and mammals that abound in the Institute. Those "8 college announcements" would lie well in the stomach of an imitation whale, and the "16 dissertations" would stiffen out very nicely the interior of the unpleasant-looking saurians which are grouped about the halls. One's sympathies are stirred at the thought of those reports, and dissertations, and announcements lying untouched in the Tall Tower. There is something touching also in the attitude of the faithful custodian who makes no complaint of the library, but only asks for more room, plus $10, for the "Index Medicus."

SEPARATE BEDS AND NERVOUS FORCE.

THE *Annals of Hygiene* preaches a curious doctrine when it says: "Much of the discomfort and nervousness which people complain of when they arise in the morning is due to the fact that each does not sleep alone. There are electrical changes going on in the system during the night, and where persons lodge together night after night under the same bedding these distributing causes work destructive results."

The *Annals* seems to think that there is some occult and undetermined electric force that works about under the bedding. Such statements are pure assumptions un-

worthy of a scientific journal. But *The Lancet* is also quoted as believing in this same force. "Nothing," says *The Lancet*, "will so derange the nervous system of a person who is so eliminative in nervous force as to lie all night in bed with another who is absorbent of nervous force. The latter will sleep soundly all night, and rise refreshed in the morning, while the former will toss restlessly, and will awake in the morning fretful, peevish, faint-hearted, and discouraged. No two persons, no matter who they are, should habitually sleep together. The one will thrive, the other will lose. This is the law."

This also is a most extraordinary kind of rubbish to appear from a scientific periodical. When, and how, we would ask, has it been discovered that some persons "eliminate nerve-force," and others absorb it? Has *The Lancet* discovered a new and potent truth not heretofore known to physics, physiology, or psychology, or is it indulging in *double entendre?*

If *The Lancet's* law be true, how is it that children thrive, that kittens grow, and that the average duration of life of the married is longer than that of the single?

We do not, however, altogether dispute the plea of the *Annals* and *The Lancet*, for there is practical truth in the point urged. But the reasons given are of the most fantastic and unsubstantial character.

STERILIZED MILK.

The warm weather brings up again the neglect of infant feeding, and in particular of the sterilization of milk. An article recently published in the *American Journal of the Medical Sciences*, by Drs. Albert R. Leeds and Edward P. Davis, is of special value on this point.

Professor Leeds has made a careful chemical study of normal and sterilized cow's milk, and he finds that there are three classes of substances which are present in normal cow's milk.

1st. Substances in suspension, including: Nuclein, an organic compound containing phosphorus, the composition of which has not as yet been satisfactorily determined. Fat-globules, destitute of envelopes, and swimming in a colloidal ("somewhat ropy or mucilaginous") fluid, the physical characters of which are favorable to their persistence as separate globules under ordinary conditions of temperature and reaction.

2d. Substances present in a colloidal condition, including: Casein and lactalbumin, the former of which appears to be in combination with alkali, and probably also with lime and phosphoric acid, and is precipitable by dilute acid.

3d. Substances present in solution, including: A nitrogenous starch liquefying ferment, "galactozymase," milk-sugar, common salt, and certain soluble compounds of phosphoric acid.

The noted effects of sterilization are: *a.* The starch-liquefying ferment is destroyed and coagulated. After coagulation the "galactozymase" is insoluble, and is carried down with and included in the precipitate obtained on addition of dilute acid.

b. A portion of the lactalbumin, as it exists along with the other substances present in milk, is coagulated. But this coagulation is only partial, even after long-continued heating. Its effect however, is to thicken the milk and intensify its colloidal (ropy or mucilaginous) character.

c. The casein is not coagulated by the heat, but is less readily coagulated by rennet, and yields slowly and imperfectly to the action of pepsin and pancreatin.

d. The fat-globules themselves are somewhat affected by the heat, and after standing lumps of butter-fat have sometimes been observed on the surface of the milk. But the coagulated proteid matters attach themselves to the fat-globules and probably have an influence in bringing about that less perfect assimilation of fat which has been noted by various observers as true of infants nourished upon sterilized milk.

The milk-sugar by long-continued heating is completely destroyed, and is probably affected to a certain extent during the interval ordinarily allowed for sterilization.

Finally, sterilized milk is less readily and less perfectly digestible than raw milk, and if sterile milk is sought for, the present desideratum is to obtain it either directly from the animal, or by a process not accompanied by such serious drawbacks.

Such a process is believed to be the heating of the milk, after being rendered feebly alkaline with lime-water, to 155° F. for six minutes; or, still better, the treatment in alkaline solution with pancreatin at 155°, followed, if not used immediately, by momentary heating to the boiling point.

Dr. Davis from his clinical experience thinks that sterilized milk is of help in checking diarrhœa and curing enteritis, but is not adapted for prolonged use in infant feeding. He has not tried the modified plan of sterilization suggested by Professor Leeds long enough to reach conclusions as to its value.

THE HYGIENE OF UNDERGROUND RAILROADS.

The present discussion of the subject of rapid-transit in this country gives special interest to an editorial in the *Medical Press and Circular* on the hygienic condition of the Underground Electric Railway in London. As is well known the Rapid Transit Commission has suggested the adoption of an underground road, the motive power being electricity, as in the case of the London road. The *Press* states that the air in this tunnel is remarkable for its purity, and for the absence of anything of the nature of a disagreeable effluvium. One odor is very perceptible, but it is that of ozone, produced, it may be assumed, by the action of the powerful electric currents by which the line is worked. Being *per se* a powerful oxidizing agent, it may doubtless be relied upon to hold in check the musty emanations which usually characterize these underground passages. "Indeed," says the *Press*, "a humorous contemporary suggests that, as ozone is the prime vivifying agent in the air at the seaside, in country lanes, and on mountain slopes, a few hours passed daily on the electric railway might not improbably have a decidedly beneficial effect on anæmic and oxygen-starved Londoners."

If our New York capitalists can build a rapid-transit tunnel which will carry people rapidly home, and at the same time supply them with a health-resort twice a day, they will be amply repaid by a grateful public.

THE THERAPEUTIC VALUE OF RESORCIN.

In Börner's "Medical Calendar for 1890" it is stated that "resorcin is a drug which is a disinfectant; as an antipyretic in typhoid fever it is useless, in acute rheumatism it is of less value than salicylic acid." These brief statements of its value does not satisfy Dr. H. Menche, of Rheydt, who has used the drug continuously for nine years, and who, in the *Centralblatt für Klinische Medicin*, May 23, 1891, gives the result of his long experience. In ordinary cases of the diarrhœa of infants Dr. Menche gives calomel in small doses, but if there is already some collapse he prescribes resorcin in doses of gr. ¼ to gr. iij. every quarter hour according to age. He can recall no case in which after a short time the vomiting and diarrhœa have not stopped.

He also uses resorcin in all cases of gastritis, gastric catarrh, and dyspepsia, giving it in doses of a teaspoonful of the one per cent. solution. The drug can be combined with rhubarb and other drugs, but should be put up in black bottles on account of its sensitiveness to the action of light.

Resorcin was also used successfully in the vomiting of pregnancy, of peritonitis, and in sea-sickness. It also acts well as a hypnotic in insomnia of phthisis, typhoid fever, and nervous irritability. It is considered very important indeed that the resorcin be free from all impurities, that it should be, in fact, *resorcin purum resublumatum albuminum.*

Resorcin has obtained some reputation as a valuable drug in whooping-cough, and also in certain skin diseases.

FURTHER PROGRESS IN MEDICAL EDUCATION IN NEW YORK.

The Medical Department of the University of the City of New York makes certain special announcements this year which should have a very general interest, indicating as they do a decided advance in educational methods. First: The Faculty have placed the College upon a true University basis; that is, the pecuniary interests of the College have been put entirely in the hands of a body separate from the Faculty, while the latter receive fixed salaries, and are free to give their time and energy to advancing the standard of the curriculum unincumbered by financial care. This step makes the Faculty quite independent of the number of students who may attend the college classes.

A second change consists in making the three years' course obligatory; and a third, perhaps the most important of all, consists in the introduction of the recitation system in place of the didactic lecture during the first and part of the second year.

A DRUG TREATMENT OF PNEUMONIA.

In a lecture on "Acute Lobar Pneumonia," by Dr. A. K. Hill (*New York Medical Times*), the writer states that the disease is infectious and self-limited. He then goes to mention twenty-three different drugs as being of use in the disease. The list is an interesting one: Aconite, veratrum, arnica, gelsemium, belladonna, bryonia albâ, chelidonium, digitalis, iodine, epicac, the potashes, calomel, nux vomica, opium, phosphorus, rhus tox. sanguinaria, tartar emetic, sulphur, arsenicum, charcoal, phenacetine, liq. ammon. acetat. A good word is said for all of these in accordance with the indications, but perhaps the most surprising endorsement is that of vegetable charcoal, which we are told will "almost snatch a patient from the pangs of death when there is profuse cool sweat, small and rapid pulse, great prostration, dry tongue, offensive excretions," etc.

Suitable and sensible remarks are made regarding the use of nourishment and stimulants, but the large emphasis laid upon drugs is surprising. We recall to our readers an article by Dr. Fenwick reviewing the results of treatment of one thousand cases of pneumonia at the London Hospital. The conclusion he drew was that the best results were obtained by the use of ice and the ice-cradle, sponging and packs, with proper nourishment and stimulants. Instead of mentioning twenty-three drugs, he mentioned four, and spoke ill of each of them.

News of the Week.

The Lunacy Law Reform League and Anti-kidnaping Union held a public meeting at Monroe, N. Y., Saturday night. Addresses were made by the National Secretary, Miss C. C. Lathrop, and others, on the imprisonment of sane people in lunatic asylums, citing cases that have been proven in court.

The Bichloride of Gold Club, at Dwight, Ill., composed of graduates and undergraduates of the Keely Institute for the Cure of Drunkenness, occupies and has fitted up handsomely for its use the abandoned Presbyterian church in that village, which was mainly built by funds presented by the Prince of Wales on his visit to this country, when he stopped four days at Dwight to shoot prairie chickens. The club now numbers five hundred members. In connection with this announcement we are anxious to learn why the Iodide of Potash Club, of Hot Springs, Ark., does not report its proceedings more regularly. Little is heard now also of the Tuberculin Club, of Berlin, Germany, or of the Bergeron Club for the Promotion of Sulphurous Injections, at one time in active operation throughout France. It must be inferred that the flow of scientific thought pulsates very intermittently. We predict a time when even the Bichloride of Gold Club will be less heard of than at present.

The Maryland Medical Journal says the Board of Visitors of the University of Virginia, at a recent meeting, decided to make the degree of doctor of medicine a two-year course—the first session to comprise anatomy, chemistry, physiology, materia medica, and bacteriology; the second year surgery, practice of medicine, obstetrics, hygiene, and medical jurisprudence. The faculty was instructed to make the necessary changes in the classes.

Charles Dudley Warner says that the difference between the "faith cure" and the "mind cure" is that the mind cure doesn't require any faith, and the faith cure doesn't require any mind.—*Albany Medical Annals.*

It is evident that Illinois is to have an insane asylum on the Illinois River, which, following the example of New York and Massachusetts, will be under the exclusive charge of the homœopaths.

Blätter fur klinische Hydrotherapie is the title of a new monthly journal, edited by Professor William Wintirwitz, of Vienna.

Constipation a Neurosis.— Dr. Dunin, of Warsaw, thinks that habitual constipation is in most cases a neurosis, due generally to the use of purgatives. He does not think it necessarily harmful if a person goes several days without a passage. Besides dietetic and hygienic measures, he prescribes bromide of potash and antipyrin.

Japan has 40,215 physicians.

An Attempt to Establish a "Home for the Dying" is being made in London. It is proposed to raise $50,000 for the purpose. The object is perhaps praiseworthy, but it is a grewsome name.

Dr. William Mottram died of apoplexy in Kalamazoo, Mich., on Tuesday, July 2d, at the age of eighty-four. He was born at Gilbertville, N. Y., and began the practice of medicine in St. Joseph County, Mich., in 1834. He has practised continuously since that time, with the exception of two years spent in professional study in Philadelphia. In 1850 he removed to Kalamazoo, where he resided until his death. He was one of the founders of the Kalamazoo Academy of Medicine, was for several years its president, and at the time of his death was dean of the Borgess hospital staff. In 1843 he was elected a member of the Legislature, and had much to do in shaping the present educational system of Michigan. Dr. Mottram was courtly in his address, and his manner was that of a polished gentleman. He leaves a large circle of friends, both in and out of the profession.

Joseph O'Dwyer, M.D., LL.D.— At the Commencement of St. John's College, Fordham, in June of this year, the honorary degree of Doctor of Laws was conferred upon Dr. Joseph O'Dwyer, of this city.

Dr. David Matthews died at his home, in this city, on July 9th, of heart disease. He was graduated from the College of Physicians and Surgeons in 1860, and served in the war as surgeon of a regiment from Orange County. He had been a police surgeon since 1877, and was sixty years old at the time of his death.

Dr. William Dounan, who died at Burgettstown, Pa., on July 9th, had practised medicine there continuously for fifty-five years. He was eighty-one years old, and is survived by his wife, whom he married fifty-three years ago.

Professor F. Peyre Porcher, M.D., LL.D.—The University of South Carolina, at its Commencement, on June 18th, conferred the honorary degree of Doctor of Laws upon Dr. F. Peyre Porcher, the well-known physician and botanist of Charleston, S. C.

Two Deaths from Hydrophobia are reported to have occurred at Fort Wayne, Ind., within the last week.

The First Meeting of the State Board of Medical Examiners was held at Albany, July 11th. The object of the meeting was to organize and to compare views in regard to the details of State examinations in medicine which must be passed by every person who wishes to practise in this State after September 1st next. Secretary Dewey, of the Regents, previous to the discussions, said that during the year ending July 1, 1890, three hundred and eighteen diplomas had been presented by physicians of other States to the State Board of Medical Examination for license to practise in this State. Two hundred and thirty-one of these diplomas were endorsed by the State Board, forty-three rejected, and forty-four are still held under advisement. The Chairman was empowered to appoint a question board of six members, to consist of two from each of the separate examining boards, for the purpose of preparing a syllabus in all departments of examination except of materia medica and therapeutics. The conference then adjourned, subject to the call of the chair. The State Medical Society Board elected Dr. Wey, president, and Dr. Fowler, of Brooklyn, secretary, and appointed them to represent the board on the Syllabus Committee. The Homœopathic Board elected Dr. Couch, of Fredonia, president, and Dr. Paine, of Albany, secretary. Drs. Wetmore, of New York City, and Searle, of Brooklyn, were designated to represent the board on the Syllabus Committee. The Eclectic Board chose Hugh J. Linn, of New York City, president, and Edwin S. Moore, of Bay Shore, L. I., as secretary. Dr. Tuttle, of New York City, and Dr. Moore were designated to represent the board on the Syllabus Committee.

Flogging and Cerebral Embolism.—The town of Pontiac, Mich., has been torn asunder for many months by the trial of a lady school-teacher for manslaughter. It seems a wayward boy was punished last year by flogging on his legs with a leather strap. It does not appear that the skin was broken, but that there was swelling and blackness of the limb. In a brief interval after this punishment the boy was taken ill and suddenly died. The prosecution asserted that a clot from the veins of the legs caused embolism of the brain. The case was tried with all the formalities, perplexities, and animosities engendered by conflicting expert testimony, but the teacher was acquitted.

Dr. William W. Jones died, July 10th, at his home in this city. He was seventy-eight years old. He was born in this city. His father was William G. Jones, and his grandfather Dr. Gardiner Jones—a prominent physician in the colonial days, and an intimate friend of Benjamin Franklin. Dr. William W. Jones was graduated from Rutgers College, and completed his studies at the New York College of Physicians and Surgeons in 1842. For two years he was resident physician at the New York College of Physicians and Surgeons. He was a member of the County Medical Society, the Academy of Medicine, and the Physicians' Mutual Aid Association. He had been a visiting physician to the Northern Dispensary, attending physician to St. Luke's Hospital, and consulting physician to the Nursery and Children's Hospital, and the New York Asylum for Lying-in Women.

Tincture of Iodine and the Peritoneum.—Fraenkel has shown that tincture of iodine and iron salts locally may cause a sero-fibrinous peritonitis. The suggestion is made that some of the peri-uterine inflammations may be caused by the iodine applications so often made.

A Temperance Medical Congress was held at Prohibition Park, Staten Island, July 15th and 16th, under the auspices of the American Medical Temperance Association.

Man's Superiority to the Animals.—It takes four men to give an elephant castor-oil, the dose being ℥ cxxviii. We have known it to take three women and two men to give a small boy castor oil, dose only ℥ j.

Pyoktanin is a Failure as an Antiseptic, says Dr. Roswell Park (*Annals of Surgery*). It cannot be relied upon in surgery except in strength that is dangerous. As an injection in gonorrhœa, he adds: "I have had no experience with it, but find that most of those who have tried it have met with disappointment. Upon granulating surfaces it does appear to be stimulating and to exert a desirable effect, but no more so than other substances within easy or easier reach, and its stain is often undesirable. In ophthalmological practice it appears also to have scarcely come up to the requirements of the day. On the whole, then, it has but few qualities by which we are to commend it above numerous other drugs of its general class, while in all that may answer to the more scrupulous demands of aseptic surgery it has proved in my hands—as in those of others who have tested it from the purely clinical stand point—disappointing."

Hypnotism in France.—The Society of Hypnology will meet in Paris on July 20th, under the presidency of Dr. Dumontpallier. The business to be done will include the organization of a Second International Congress of Hypnotism, to be held in 1892. Among the subjects proposed for discussion are the following: "The Relations of Hysteria to Hypnotism;" "Criminal Suggestions and Penal Responsibility;" "The Reality of Maternal Impressions on the Fœtus." Notice of communications, etc., should be sent to Dr. Bérillon, 40 *bis*, Rue de Rivoli, Paris.

How to Collect Physicians' Bills.—The rulings of the courts on the question of collecting bills are of the most intense and exciting interest to physicians, and it is with this in mind that we present a recent decision of the General Term of the New York Supreme Court. In this case a physician rendered medical services to the wife, and in a suit to recover the value of his services, made the husband and wife both defendants. On the trial the plaintiff was asked whether he relied on the husband or the wife for payment, and the question was allowed, although objection was made by the defendant. He replied that he relied on the wife. The case was decided against the defendant, and she appealed. The Court held that the question was improper, and directed a new trial. The ground of the decision was that the facts of the case were to decide who was liable for the bill, and that the physician could not settle the matter by declaring his intention to be to hold the wife responsible instead of the husband.

The Total Cost of Fees in the London medical schools is about $650, in American colleges it ranges from $140 to $300. On the other hand, the London schools give nearly twice as long a period of instruction, so that in reality the cost is about the same.

A Japanese Medical Nobleman.—The Emperor of Japan has named Dr. Hide Miyake, professor in the Medical Faculty of the Imperial University of Tokio, a member of the House of Peers.

The New York Board of Police Surgeons.—Eighteen physicians are employed by the Police Department to look after the health of the force, at an annual cost of over forty thousand dollars. These places are much sought after, as they are considered about as desirable as any in the gift of the Police Department. The doctors receive a salary of $2,250 per annum, and, unlike all the other members of the police force, are not required to devote their whole time to the service of the department. They are permitted and have ample time to attend to patients outside of the department, and many of them have lucrative private practices. The police precincts are divided into eighteen surgical districts, and to each district a doctor is assigned, whose duty it is to attend to the sick policemen in his own district. When an officer reports sick, the surgeon of the district is at once notified to take charge of him, and during the time that the officer is on the sick list he is entirely under the doctor's orders. When he is sufficiently recovered, the doctor orders him on duty again. The doctors in the service of the department form what is known as the Board of Surgeons, which is at present presided over by Dr. S. G. Cook, who was elected by his associates as Chief Surgeon. The board meets monthly to pass upon such matters connected with the health of the force as may be referred to it by the Police Commissioners. Members of the force who, from injuries received in the service or from other causes, have become physically or mentally disqualified from performing duty, are examined by the Board of Surgeons, and upon its certificate of such disability the disabled officers are retired from active service and placed on the pension roll. The Board of Surgeons is also required to make an annual report to the Commissioners upon the sanitary condition of the force and of the station-houses and other buildings used by the department, and to suggest and recommend such alterations or improvements as are deemed necessary for the health, comfort, or greater efficiency of the force.

Legible Prescriptions.—There are advantages in living under a paternal government, says the *British Medical Journal*, which even Mr. Herbert Spencer may be disposed to admit. The Austrian Minister of the Interior has recently issued an ordinance that the burgomasters of all communes must exercise strict supervision over the medical men practising within their jurisdiction in the matter of legibility of prescriptions. They are charged to see that every prescription is clearly and legibly written in all its parts, so that there may be no doubt as to the remedy, the dose, or the signature.

Tea-Drinking is said to cause cold feet.

Vaginismus has made its appearance as a factor in the plots of fiction. The *Lancet Clinic* states the romancist Viquet, in his "L'Eternelle blessu," has made a psychological study of two beings united by marriage but separated by vaginismus, in which there is a continual struggle between love and constrictors. In one chapter he describes how.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, May 11, 1891.

WILLIAM T. BULL, M.D., CHAIRMAN.

Osteo-Sarcoma with Secondary Growth.—DR. SAMUEL LLOYD presented a girl, about four years of age, who, eighteen months before, had fallen, injuring the forefinger of one hand slightly. Later a growth showed itself, and when Dr. Lloyd saw the patient about seven months ago, the whole phalanx was involved in the growth, which was apparently bony. The diagnosis at this time was of probably syphilitic or tubercular ostitis. The growth was rapid. Two or three others had since appeared, one on the upper portion of the ulna of the the same member, another on the other hand. The behavior of the growths and the microscopical examinations had since led to a diagnosis of sarcoma. The parents had refused an amputation, and the treatment had been by injections of pyocyanine (pyoktanin?). The tumors which had not been injected had grown more rapidly than the others, and the side of the same tumor not injected had grown more rapidly than the injected side. If this method should not succeed the parents had given their consent to inoculation with the virus of erysipelas.

THE CHAIRMAN said he had had experience in only two cases with the method of treatment described by Dr. Lloyd, and after about two weeks the swelling and inflammation had been so increased that the patients refused further trial.

DR. LLOYD said he had arrested the growth of an epithelioma of the lip, causing it to cicatrize, by laying on it a compress saturated with 1 to 500 solution of pyocyanine.

Four Cases of Gun-shot Wounds of Cavities.—DR. THOMAS H. MANLEY reported the four cases (see p. 65). One was a case of gun-shot wound of the skull, the ball entering through the temporal muscle on the right side. It was found, after a crucial incision had been made, lying against the dura, which it had not penetrated. It was removed without difficulty. There had been no paralysis, no unconsciousness, very slight shock, no rise of temperature until the third day, when it went up to 101° F. The patient then vomited two or three times, and after the wound had been dressed complained of a violent headache, and in three hours was dead. At the post-mortem examination nothing was found to account for death. There was slight disintegration of cerebral substance.

In another case the bullet entered about an inch and a half above the left nipple, three and a half inches above the median line, passed through, penetrated the scapula an inch and a half from its outer margin, was cut down on and removed from beneath the skin. The effusion of blood was so great that the heart was thrown completely to the right side. The wound was kept open. On the fifth day the temperature went up to 104.5° F., there was local pleurisy, and decided symptoms of sepsis. He therefore enlarged the wounds freely anteriorly and posteriorly, and washed out the pleura, after which the fever subsided. The accumulation having disappeared, the heart swung into position and the patient finally recovered.

A third case was the only one known to him in this country in which a gun-shot wound of the stomach had been sutured. Like the previous patient, this man shot himself with suicidal intent. Dr. Manley saw him two hours after the injury, when he was in a state of marked shock. He vomited blood, mucus, and partly-digested food. The wound was two inches and a half below the left nipple. Performing laparotomy the peritoneal cavity was found perfectly dry, yet he felt confident from the vomiting of blood that the stomach must have been penetrated. After trying to trace the bullet toward the right kidney, where the patient complained of burning pain, he then passed the hand upward to examine the stomach whereupon blood was expelled freely from the stomach into the peritoneal cavity. Considerable difficulty was experienced in drawing the wound down so that it could be sutured. Things went along well for three or four days, until pleurisy with effusion took place, and the patient finally died. The case showed the interesting fact that there could be one or more perforations of the stomach without effusion into the peritoneal cavity.

The other case was one of self-inflicted gun-shot wound followed by both hæmoptysis and hæmatemesis, and there seemed to be no doubt about perforation of the stomach. The man was expected to die before the next morning, yet without an operation he made a good recovery. Others had reported cases of penetrating gun-shot wounds of the stomach in which, without interference, recovery had taken place.

Drainage in Abdominal Surgery.—DR. DUDLEY P. ALLEN, of Cleveland, O., read the paper by invitation. He divided the topic into three heads: 1. Is drainage of the abdomen after operation ever desirable? 2. If desirable, in what cases should it be employed? 3. When to be employed, what method should be chosen?

When treating wounds generally he kept in mind three points, namely, to observe asepsis, to bring the surfaces into and preserve them in close coaptation, and to avoid fluids accumulating between the surfaces, thereby causing them to separate. In a degree the same rules applied in abdominal surgery. The author here spoke of the accumulation of fluids in the abdomen after operations, and said he thought the tendency in this direction was not strong except there were sepsis or hemorrhage. The ability of the peritoneum to dispose of fluids was well known. If, then, there were certain forces tending to restrict the accumulation of fluids in the abdominal cavity, and also a force tending to remove them after they had collected, the question arose, what fluids could be safely left to natural means, and what ones should be removed? Those which could be left were serous oozing from wounded surfaces and small collection of blood. Fluids which were dangerous to leave were large amounts of blood, and pus or septic material. But while leaving a large amount of blood was to be deprecated, he doubted whether leaving a small amount was so objectionable as some thought it was. He strongly suspected that cases in which large amounts of serum had been removed by drainage were cases in which there was a tendency for this fluid to accumulate before the operation.

Cases Requiring Drainage.—The abdominal cavity should be drained: 1. In septic peritonitis; 2. Only rarely in cases of gunshot wounds. In the few cases which he had seen he had been surprised at how small was the amount of fecal material extravasated, even when the lumen in the gut was large. He believed that all that could be accomplished was thorough cleansing of the abdominal cavity without drainage. 3. Tubercular peritonitis. This presented itself under various forms, and might be operated upon at various stages. 4. Operations for peritonitis where pus was present, or adhesive inflammations had prevented removal of all foreign material. 5. Intestinal obstruction in certain conditions. But the impression had grown on him that where there was in these cases free fluid, not septic, in the cavity, it was not necessary to drain. But if it were plastic and infected, drainage was indicated. 6. Hemorrhage. It was better, however, to take steps to prevent much hemorrhage rather than trust to drainage. It had been his experience that troublesome and deep hemorrhage could be admirably controlled by catgut suture. He was not one who believed that a small opening in the abdominal cavity was of primary importance when standing in the way of full knowledge of the condition within. 7. Extra-uterine pregnancy. In operations for this condition drainage was

sometimes indicated. It was not always possible to completely remove the products of fœtation, and sometimes was unwise to remove the placenta. 8. Adhesions. It was his belief that divided adhesions did not furnish in themselves cause for drainage. 9. Escape of cyst contents into the abdominal cavity. When this occurred, and the fluid was infectious, no precaution for its removal could be too great; then wash and drain. 10. Pyosalpinx. Until we should know more concerning the character of pus and the propagation of various forms of bacteria, it would be wise to act on the supposition that all pus was infectious. If pus had not escaped, and the cautery were used, he would regard drainage as unnecessary. But if pus had escaped, or the operator was uncertain whether there had not been infection, or if part of the tube were left, it would be wise to drain. 11. Pelvic abscess. If pus was likely to form subsequently, there should be drainage.

In conclusion, he said that the ideal form of laparotomy was that in which the abdominal cavity was closed at once. Anything which would obviate the necessity for drainage would be a step in advance.

Dr. W. M. Polk being asked to open the discussion, said that the object of the paper was, as far as he could judge from that portion which he had heard read, to limit, if not entirely do away with, drainage. He thought all could sympathize with this object, not alone for the reason that drainage meant possible further inflammation, but also because of the possibility of the abdominal wall giving way if not properly brought together at the initial operation. He must confess that the latter objection was the only one which had much weight with him in the work which he had been called upon to do. He was well aware that a good deal had been said concerning the efficacy of intestinal drainage, but those of us who had seen patients die of peritonitis when they had diarrhœa, realized the importance of drainage. Therefore, the plan which he had adopted was to drain in every doubtful case. That implied every case which was liable to any residuum whatever in the peritoneal cavity, even if it were only ascitic fluid, the result of chronic peritonitis, which, probably, was about as innocuous as any. If the patient could not be kept quiet, use the gauze drain instead of the tube. It was to be borne in mind, however, that the gauze drain left a larger opening than the glass tube. It might be desirable to use both in a given case.

Dr. W. Gill Wylie said he could see little to object to in the paper. Like Dr. Polk, he always drained in doubtful cases. He had tried to formulate rules, but in practice had found it best to decide whether to drain or not to drain at the operation. If he washed the abdominal cavity out, he left a drain which could be removed within twenty four to forty-eight hours. It did away with the necessity for sponging, which caused irritation. He had lost some patients by not draining, but knew of no instance in which death could be attributed to drainage. An important point was the time when the drain should be removed. Where infectious material had escaped, or a portion of a pus-sac had been left in the stump, the drain should remain in longer, say three or four days, giving sufficient time for any septic material to show. The risk of hernia was practically *nil* when only a small tube was left in, and the wound was closed by suture when the tube was removed. In some cases he preferred to insert alongside the tube some gauze, although the danger of subsequent hernia was greater.

Dr. Syms would drain where there had been septic material in the abdomen, but the difficulty was in deciding whether material was or was not septic. The combined glass and gauze drain was superior to either used singly.

Dr. Clement Cleveland said that at one time he thought every laparotomy case would be benefited by the insertion of a drainage-tube, but he had long since got over that idea. At present he never used drainage after removal of a simple tumor, but limited it to cases in which there was pus, or in which, owing to separation of adhesions, there was danger of capillary hemorrhage. He favored gauze and lamp-wick.

Dr. Thomas H. Manley used the drainage-tube only where there was pus or some irritating fluid. He thought its field of usefulness was becoming more limited.

Dr. Wylie added that the drainage tube had sometimes proved useful in cases where hemorrhage was feared, in showing whether this was or was not really the cause of any subsequent symptoms.

The Chairman said that in general he quite agreed with the suggestions contained in the paper. One disadvantage of drainage had not been mentioned, namely, the liability to troublesome sinus. It also sometimes caused inflammation in the wound. Thus, while he was disposed to drain whenever in doubt, yet he liked the idea of securing primary union throughout whenever it was safe. Like the author, he had found it exceptional that the glass tube secured sufficient drainage from dependent situations. He now relied more upon iodoform gauze.

Dr. Allen closed the discussion.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 11, 1891.

H. M. Biggs, M.D., President, in the Chair

Ectopion Pregnancy.—Dr. H. J. Boldt presented two specimens of this condition, in one of which, the embryo was shown *in situ*. In the first case, the patient was thirty-three years of age, had had one child and one miscarriage. In January, 1885, she was treated for endometritis and catarrhal salpingitis. On November 9, 1890, four weeks and two days after the last menstrual period, she became unwell, and suffered from cramp-like pains. The flow continued pretty constantly up to January 17, 1891, when she again came under the speaker's care. At that time, she was suffering intense pain in the right ovarian and lumbar regions, and the discharge from the uterus was thick, of a dark chocolate color, and had a disagreeable odor. The uterus was slightly enlarged and softened, and a little to the left of the median line. To the right was an enlarged and sensitive Fallopian tube; the left tube was normal. She was sent to the operation-room, but at the time of the operation, she was almost pulseless, and exsanguinated, and no tumor could be felt. It was supposed that the tube had ruptured, and on opening the abdomen this opinion was confirmed, as the abdomen was filled with blood. The bleeding tube was tied off, and the abdominal cavity cleansed with hot water and closed. Recovery was uninterrupted.

The second specimen, containing the embryo, was removed from a woman, thirty-three years of age. She had had an abortion two years before, and three children, the last one ten years previously. About one year before she had suffered from uterine hemorrhage due to a fungous endometritis, which was cured by curetting. She had had also a salpingo oöphoritis on the left side. From November 29, 1890, to January 25, 1891, she had increasing pain in the left ovarian region, and on the latter date there was a profuse hemorrhage. She was seen in consultation on February 7th, and the uterus was found to be pushed upward and forward and somewhat to the right by a tumor which was connected to the left of the uterus. The patient was exsanguinated, the pulse was 140, and very feeble, and she suffered much from periodical cramps in the region of the tumor. A diagnosis of ruptured tubal pregnancy was made, and before the operation, on the following day, there were symptoms indicating an additional intra-peritoneal hemorrhage. She also made an uneventful recovery.

Ordinarily, a case presenting the signs and symptoms detailed in the foregoing histories would lead one very readily to make a diagnosis of tubal pregnancy, and if the symptoms point to a probable intra-peritoneal hemorrhage

an operation should be promptly performed. Where such hemorrhage is quite profuse the speaker thought it was advantageous to leave a large quantity of a physiological saline solution in the abdomen, and to close the abdomen. In speaking of the prominent symptoms he had purposely refrained from referring to the passing of a decidua, for in his experience, this so-called deciding symptom had been conspicuously absent. It was also interesting to note that in all the cases which he had seen there was a history of catarrhal salpingitis, thus rendering it probable that tubal pregnancy does not occur in cases where the tubes are normal.

Dr. Boldt also presented a large intra-mural myofibroma, which he had removed by supra vaginal hysterectomy from a virgin, forty-six years of age. Profuse menstruation had been present for six years, but the tumor had given scarcely any inconvenience until about two months ago, when the incarceration of the lower lobe of the fibroid in the pelvis suddenly gave rise to very severe reflex symptoms, such as oppression about the chest, tachycardia, and intense pains along the course of all the principal nerves. The operation was performed on March 1st, since which time the temperature had remained normal, and the pulse instead of being feeble, and 140, was 80 to 90 and of normal strength.

Dr. Boldt also exhibited two specimens of fibromata which had been treated unsuccessfully by electrolysis. He had seen many cases in which electricity had proved not only useless, but actually dangerous, by causing sloughing and favoring sepsis. A perusal of the literature of this subject shows a remarkable discrepancy in the dosage of this powerful agent as employed by different operators, some stating that they use from 250 to 350 milliampères, while others find that their patients will not tolerate more than 100 to 150. The majority of patients will not bear a current above 75 milliampères. In one instance, he had proved this discrepancy to be due to the inaccuracy of the meter, and he believed that this observation applied to many other instances.

Dr. Boldt also showed a small ovarian cystoma which he had removed by opening Douglas's cul-de-sac. In the majority of cases he had found this operation preferable to the abdominal method.

A New Clinical Chart.—Dr. J. H. Linsley presented a chart which had been devised by Dr. Bailey and himself particularly to meet the demand for a quick and accurate method of keeping complete histories of cases undergoing Koch's treatment, but its sphere of usefulness was not confined to such cases.

Dr. Boldt thought this chart was one of the best of its kind he had ever seen; and when one considered the immense amount of time consumed in writing histories in the usual way, and the great liability of omitting small but important details, the utility of such a device was evident.

Dr. S. T. Armstrong said that for the past six years he had been using figures representing different sections of the body, and so arranged that they could be easily gummed to the regular clinical history forms. He had been obliged to purchase these in London, and was glad that the subject had been taken up in this country. Quite recently a Brooklyn physician called attention to the advantage of using rubber stamps representing different portions of the body.

Tubular Angio-Sarcoma.—Dr. Eugene Hodenpyl presented gross and microscopical specimens of this rare condition. They were removed with one-half of the lower jaw from a man about forty-five years of age. The tumor, which was about the size of a small orange, was situated beneath the periosteum, completely surrounding the jaw at a point midway between the angle and median line anteriorly, and involving the bone.

These tumors would seem to be quite rare, as Heidenhain, in an article published in 1890, found only ten recorded cases. The specimens under the microscope showed small acini, apparently lined with flat cells, and containing in their centres endothelial cells, and masses of blood-globules. Klebs considers these acini to be really blood vessels. In order to contrast this specimen with those of other sarcomata, Dr. Hodenpyl also exhibited two other specimens; one of a sarcoma, in which spindle cells were arranged around the blood-vessels, and of a sarcoma of the liver, where the blood-vessels were lined by endothelium, and around them were to be seen large flat cells.

Dr. T. M. Prudden thought this class of tumors particularly interesting, as their true nature was often overlooked. It was well known that sarcomata had their origin in immediate association with the blood-vessels, and that many of the characteristics which they show in the early stages, and which are dependent upon the blood-vessels from which they arose, are lost sight of as these growths continue to grow; but in the peculiar form under discussion, these features, instead of being obliterated, become the predominating ones. The changes taking place in the endothelial cells, and particularly in those of the blood-vessels, merited much more careful study than they had hitherto received.

Cancer of the Pancreas.—Dr. S. J. Thacher presented such a case, which was chiefly of interest on account of the misleading character of the prominent symptoms, hæmatemesis. A seamstress, sixty-five years of age, was admitted to St. Luke's Hospital, eleven days before her death. She had been in pretty good health up to six weeks before this, when she became slightly jaundiced, and suffered from vomiting and tenderness in the upper portion of the abdomen. The stools were light-colored, and the urine dark. On admission, the history states that the liver extended from the fifth rib to within one inch of the umbilicus; there was marked jaundice, and purpuric spots over the chest and abdomen. The urine contained bile-pigment, but no sugar, albumin, or other abnormal ingredient. A day or two later there was considerable tenderness, and a sense of resistance just above and a little to the left of the umbilicus. On examination of the contents of the stomach showed absence of hydrochloric acid, and the stomach-tube brought away considerable dark, grumous material. Intense jaundice and repeated hæmatemesis were the principal symptoms, and were explained by some of the physicians as being due to carcinoma of the stomach, and by others, as a consequence of hypertrophic cirrhosis of the liver. At the autopsy, the stomach was found to be normal, as was also the heart, lungs, and spleen. The lower border of the liver was half an inch above the free border of the ribs in the right mammary line. The gall-bladder was distended with black, viscid bile, and on the surface were about one dozen nodules, apparently carcinomatous. Moderate pressure was sufficient to cause the bile to flow freely. The head of the pancreas was enlarged, adherent to the duodenum, and at this spot there was an ulcer, two inches in diameter, nodular, and infiltrated, and carcinoma involved the muscular coats as well as the other coats of the duodenum. The remaining portion of the pancreas was so greatly atrophied that is was impossible to demonstrate from the gross appearance the existence of glandular tissue.

In connection with this case, Dr. Thacher said he desired to report another, which he had examined post mortem, and which presented some similar features. A colored man, fifty years of age, was delirious when admitted to the Presbyterian Hospital, two days before his death. The friends stated that for about six months, he had had pain in his back, had vomited occasionally grumous material, and had had quite recently, jaundice, and dark diarrhœal movements, containing mucus streaked with blood. On admission, he was decidedly emaciated and slightly jaundiced, and near the umbilicus was a symmetrical, conical, and slightly fluctuating tumor. Its surface was slightly nodular, and apparently continuous with the liver substance. The urine contained some bile. His pulse and temperature were nearly normal. At the

autopsy, the lungs were found œdematous, the heart and spleen were small, and the stomach contained considerable mucus, but was otherwise normal. The gall-bladder measured 6x3 inches in diameter, and was filled with black, viscid bile, the gall-ducts in the liver were much enlarged, and the markings of the liver were dark and fairly distinct. The head of the pancreas was replaced by a large, firm, nodular mass, 5x6 inches, which pressed upon the pylorus, and sent projections into the duodenum, which were ulcerated for five and a half inches along the duodenum. To the left of this mass, the glandular tissue was atrophied, and another mass was found adherent to the left supra-renal capsule.

In answer to a question as to the points of differential diagnosis, Dr. Thacher replied that the jaundice pointed probably to pressure on the bile-ducts, and the hæmatemesis to rupture of blood-vessels, and cancer of the head of the pancreas best explained both of these symptoms.

Tuberculosis of the Lung, Showing a Peculiar Distribution of the Lesions.—The President presented such a case. The patient, who was suffering from dementia, was only in the hospital for twenty-four hours when he died, almost instantly. The previous history was not very satisfactory, but there was nothing to suggest pulmonary disease. At the autopsy, the brain showed very marked thickening of the pia, with œdema, dilatation of the ventricles, and granular ependymitis. With the exception of one lung, the other organs of the body were practically normal. The upper lobe of the left lung was normal, excepting a slight amount of senile emphysema. At the upper portion of the lower lobe, were two or three small cavities, and extending down from these, a large number of cheesy tubercles, the lower portion of this lobe being filled with the minutest kind of miliary tubercles. Careful search failed to show the slightest tubercular change anywhere else in the body. Only two explanations of this condition seemed plausible, viz., either that a foreign body pneumonia had been excited by the entrance of some foreign body containing tubercle bacilli, or else that a small tubercular process had been confined to the lower lobe, until it had broken down, and that then the products of disintegration had been distributed by aspiration throughout the lower portion of the lung.

Papillary Adenoma of the Kidney.—The President also presented a specimen of this condition. It had been removed from the kidney of a man, seventy-eight years of age. These adenomata of the kidney are comparatively rare, but are more common than is generally supposed, as they are often mistaken for fibromata, tubercular masses, and in some instances, where they have undergone change, for the colloid cystic masses occasionally found in the kidney. Wechselbaum and Greunig say that after seventy years of age they occur in ten per cent. of cases, and that they are usually multiple and commonly of small size. When multiple they are very important clinically, because they are often mistaken for carcinomata, and in one case in which Dr. Keyes removed the kidney it was found to contain a very large number of these adenomata. A competent pathologist who examined the growths, pronounced them carcinomata, although a subsequent examination which Dr. Biggs had made of the recently formed tissue, showed a characteristic adenoma. The clinical history of the case also confirmed the diagnosis of adenoma, for it was nearly two years since the operation, and the patient was still perfectly well.

Dr. Prudden said that he had once seen in a child a lung which was very similar to that just presented by Dr. Briggs, and he had considered that the peculiar distribution of the lesions was due to breaking down of a tubercular mass, and a subsequent dissemination of these products by aspiration. He had reported some years ago to this Society a series of cases of adenomata of the kidney in which the growths were larger than the one just presented. The cases had all pursued a benign course.

The Society then went into executive session.

Correspondence.

THE HANK TRUSS.

To the Editor of the Medical Record.

Sir: It seems strange in these days of progress and enlightenment that we should go back, select and advocate a method of treatment that has long since been tried, found wanting, and condemned to innocuous desuetude. I refer to the article published in the Medical Record of May 30th, on "The Treatment of Hernia by Means of the Hank Truss."

The danger of excoriation the writer speaks of, from the use of any other form of apparatus than the hank, is to be credited only to those who do not known how to apply anything that requires the slightest amount of mechanical skill, or do not wish to devote the necessary time to it.

Another statement is that considerable technique has to be acquired before protrusion can be prevented, especially when dealing with a restless child. As regards "considerable technique," there are a great many mothers who can apply this form of bandage (it isn't anything else) as well as any physician, and often do, instinctively it seems, before consulting him in regard to future treatment.

During my service at the New York Post-Graduate School and Hospital I have witnessed a number of cures effected by mechanical means alone, but there was not one of them attributable to the hank bandage. I have also removed a number of them that were put on as a temporary bandage, before bringing the child to the clinic for treatment, by the mother or by physicians of other institutions.

In not a single instance was the child being benefited by this method of treatment, or showed the slightest tendency to a cure.

Among the advantages the author claims for the hank over other forms of apparatus is the absence of spring or severe elastic pressure, therefore, a less liability to excoriation or sloughing. The statement I made in the first part of this communication covers this ground. In addition I would like to state that I have applied a spring truss to an infant seven weeks old, with a double scrotal hernia, duration since birth, both about the size of a small egg, pelvic measurement nine and a-half inches in circumference, and who was wearing a hank bandage that did not even retain a portion of the gut. In fact the right hernia had formed some slight adhesions which were readily broken up under manipulation. The above is only a single example of a number of such cases. It is not an uncommon thing for me to apply spring trusses at a much earlier age.

The truss has held him perfectly since the day I applied it, and has not even reddened the skin at any point of contact, let alone excoriate him.

There isn't any form of truss, no matter how carefully applied, but will excoriate the child if the parent is dirty in habits and neglectful.

The form of truss I use is the Hood pattern, made of German-silver, covered with rubber tubing, hard rubber front and back pads and with the exception of a short strap that connects the back pads there is not anything that water can injure; this may be removed when bathing the child without fear of the truss slipping out of place.

If that is not as simple and a great deal cleaner than the hank bandage, which, in a couple of days becomes saturated with urine, coated with fecal matter, is constantly wet, rubbing against the skin at every movement, and doing more to excoriate children than any other form of apparatus, then I am greatly mistaken. The above is no exaggeration, but is the condition I have found them in.

You can get but slight pressure, and that only over the

external ring, by either the hank or elastic truss. The bulk of the pressure comes over the upper portion of the hip, just the part where it is of no use, and you do not want it.

The regulation of pressure without removing the bandage is of no advantage whatever. The hank bandage does more to weaken the tendinous and muscular structures than any other form of truss, because it does not keep the rupture back in the abdomen where it belongs. It may possibly keep it out of sight and above the external ring, but it does not keep it out of the canal and internal ring.

Truss pressure to be of any service should be over the internal abdominal ring, and not the external. Keeping a hernia out of sight is not keeping it where it belongs. It belongs in the abdomen, and to retain it there the pressure must be over the internal ring; this cannot be accomplished by the hank bandage.

Respectfully,

S. Irving Roome, M.D.

New York City.

THE RIGHT-ANGLE CONTINUOUS SUTURE.

To the Editor of the Medical Record.

Sir: In my article upon bowel surgery in your issue of June 27th, I remarked that so simple a stitch as the one which I therein described, and believe to be the best, must probably be known to many surgeons as a suture; but that I had not anywhere seen it noted among intestinal sutures.

To day I have received a reprint from Dr. H. W. Cushing, of Boston, which describes, and recommends as best, this same stitch, under the name of the "Right-Angle Continuous."

I worked out for myself this problem of the best suture, not knowing of Dr. Cushing's previous labors in this line. He is, of course, entitled to priority, and I am pleased to find that we are agreed as to the most desirable method. Very respectfully,

Robert H. M. Dawbarn, M.D.

New York, June 30, 1891.

SOME DANGERS TO WHICH EPILEPTICS ARE EXPOSED.

To the Editor of the Medical Record.

Sir: Having noticed Dr. Harcourt Anderson's communication under the above heading in the Medical Record of June 20, 1891, I wish to call Dr. Anderson's and your readers' attention to a letter of mine, published in the Medical Record December 21, 1889, entitled "How to Prevent an Epileptic Who Falls in the Street from being Committed as a Drunkard."

In my letter I published the following case: "John Wiesler, 606 East Fourteenth Street, an inoffensive, sober, poor working man, is epileptic.

Twice he happened to have an attack of his disease in the street; each time he was arrested, and, on the erroneous charge of drunkenness, first fined ten dollars, the last time sent to Blackwell's Island for ten days. He served this term from September 4, to September 14, 1889.

The man speaks German only, and had certainly no opportunity to explain himself or to communicate with his wife and child while he was under sentence.

I suggested that medals should be worn by epileptics; these medals should be familiar to every policeman; there should be a certain mode of attachment and a certain part of the body where they would have to be looked for (for instance they might be attached by means of a rubber band around the neck—like the checks of valuables in the surf baths) and by means of these medals policemen would be enabled to distinguish an unconscious epileptic from a drunkard.

Of course the precaution suggested by Dr. Anderson is much better than the one I suggested, but unfortunately there are poor epileptics like my patient, who cannot avail themselves of this best of all protections.

In bringing the case of John Wiesler, which is only one of the great many which happen, through your columns, before the medical profession, I hoped the crying wrong described would be noticed and acted upon by some of our societies, for instance the Medico-Legal Society, but thus far I have not seen that this subject has been taken up.

I spoke of my case to Police Superintendent Murray, who approved of my suggestion. Meanwhile we gave Wiesler a letter to be carried always in his pocket, and addressed to policemen and police judges who might happen to have to deal with him again.

A. Rose, M.D.

230 Second Avenue.

THE FIRST HIP-JOINT AMPUTATION IN AMERICA.

To the Editor of the Medical Record.

Sir: I see in your issue of June 20th, that Dr. Hubbard, of Fuerte, Mexico, undertakes to correct you in regard as to who was the first American surgeon that performed the operation of amputating the thigh at the hip-joint. Dr. Hubbard puts it as late as 1845, by Dr. John Swat, of Maine.

If you will turn to page 640, of Vol. 11, of Velpeau's "Operative Surgery," Wood & Co., New York. 1847, you will see that Dr. V. Mott, of New York, was the first one, October 7, 1824, and it was a success The case was reported in the Philadelphia *Journal of the Medical and Surgical Sciences*, 1827, Vol. 14, pp. 101–104.

I trust that this will be satisfactory to all.

I am, yours very truly,

Cheves Bevill, M.D.

Winfield, Ark., June 29, 1891.

To the Editor of The Medical Record.

Sir: Dr. Hubbard's cited case in the Medical Record of June 20th, of successful amputation at the hip joint in America, is long subsequent to that of Dr. Walter Brashear, of Bardstown, Ky., which was performed, I believe, in 1809.

The operation is tersely described by its originator in a letter by him to the translator of Velpeau's "Surgery," written about the time that the operation of which Dr. Hubbard writes was done.

He is the subject of this reputed pun by General Jackson, at a banquet where Dr. Brashear failed to drink a toast to the further confusion of the British, "Let Brashear alone. He has them on the hip."

A point of rather unusual interest in this connection is that this operation differed from that which now bears Furneaux Jordan's name only by the absence of any attempt to save the periosteum of a portion of the femur.

I am, sir, yours respectfully,

Will F. Arnold, M.D.,
Assistant Surgeon, U. S. Navy.

Navy Yard, Brooklyn, N. Y., June 24, 1891.

VOCAL FREMITUS IN PNEUMONIA.

To the Editor of the Medical Record.

Sir: In your issue of June 20th, I notice an article by Dr. C. N. Haskell, of Bridgeport, Conn., in reply to mine of an earlier date, upon "The Diagnostic Value of Vocal Fremitus in Pneumonia." I am very glad that the question has been raised, for it makes us think, and thinking will make us brighter and better observers of what exists. I wish, however, the writer had confined himself to direct

personal observations instead of indulging in a repetition of old-time assertions. Imputing ignorance to me adds no strength to his own argument. His opinions may be valuable, but the facts are what we want.

Allow me to point out some of the inconsistencies of his position. In his opening paragraph he says (and rightly too): "There may be cases of pneumonia in which the bronchi, large and small, are completely filled with inflammatory products. In such cases vocal fremitus may be absent." But farther on, describing a typical case of pneumonia in which the air-cells and infundibula are filled with exactly the same products, he claims that vocal fremitus is increased. We agree that "the art of physical examination depends upon fixed laws." By what freak of those laws can he explain the absence of vocal fremitus in one case and its increase in the other? The conditions are just the same except in degree.

Can any logical mind fail to see the point? A certain amount of infiltration, as in ordinary pneumonia, increases vocal fremitus; but, *mirabile dictu*, a little more of the same sort stops it altogether!

O! But he explains: "A large bronchus is plugged, which prevents the vibrations from reaching the consolidated tissue." How can it if that plug is a better conductor of vibrations than the air?

Of course the plugging of a large bronchus will diminish vocal vibrations. That is just what I have tried to show. It was the "Newton's apple" which first attracted my attention. Will not the plugging of a small bronchus, a bronchiolus, or even a minute air-vesicle do the same in its proportionate degree? Do I make myself clear?

He objects to my comparison of the violin which Professor Leaming declares in his work "is formed on the model of the human chest." Very well, I will not insist; let him take the chest itself. Authorities agree that vocal fremitus is increased with the formation of cavities. Develop this thought a little. Remove one entire lung from the thorax, and make a cavity as large as you can. Insert a tube into the glottis, and produce fremitus with your own voice, place your hands upon the chest-walls as in palpation, and tell me upon which side you find the greater thrill. I think you will say the empty one. Very well, if normal lung-tissue is a hindrance to vocal vibrations because of its bulk, with even its slight density and elastic cells, how much greater must be its resistance when that density is increased, that elasticity gone, and those cells filled with the products of inflammation instead of air.

It is a good thing for a man to leave his medical primer once in a while and think for himself.

Respectfully,

J. P. RAND, M.D.

ALBUMINURIA IN ITS RELATION TO LIFE INSURANCE.

To the Editor of the Medical Record.

SIR: I have just had my attention called to the editorial in your issue of the 20th inst. on "Normal Albuminuria." The subject is of the greatest importance to insurance companies and also to all persons who desire to avail themselves of this means of providing for their families. I think that albuminuria is a very much rarer condition than we are led to suppose. My own investigations of over three thousand applicants during the course of a year showed a percentage of $1\frac{1}{10}$. The urine was carefully examined in each case by competent examiners and either heat and nitric acid, or the cold nitric acid (Heller's) test was used. I am certain that the percentage given by Dr. Lewis, of Hartford (six to ten per cent.), is entirely too high, unless he used some of the very delicate tools, which in my opinion are not available for life insurance work. I am certain that heat and nitric acid are sufficiently accurate for our purpose, and, moreover, I think that our statistics should be based upon one standard test in order to be of any value. My percentage may be rather low and I am willing to concede an average of about three per cent., but this, I notice, is what you quote as being the mortality for kidney disease. I therefore conclude that in the usual tests for albumin most companies require we have a sufficient measure to exclude most cases of kidney disease, and that there is no necessity whatever for our using the very delicate tests, as Posner's picric acid, etc., which show traces of albumin that alarm us unnecessarily.

There are (very rare, I believe) cases of transient albuminuria that would be safe for companies to take for short endowments, but under the limitations as given by Dr. Davis, of the Union Central Life, in his excellent paper recently published by you.

Yours truly,

JOHN M. KEATING, M.D.,
Medical Director, Penn Mutual Life of Philadelphia.

June 22, 1891.

MERCURY BY INUNCTION OR INJECTION.

To the Editor of the Medical Record.

SIR: I read in the MEDICAL RECORD of May 23d, ult., a communication from Dr. J. Hunter Wells, in which he refers to the fact that the injection method (*i.e.*, of mercurials) is not yet popular in this country.

I am of the opinion that it is not yet popular in any country. In 1889 the method was still under trial in the clinic of Professor Kaposi at Vienna, one of the trials resulting in the death of a strong woman of some thirty years of age, on whom three (3) injections had been made. At the autopsy, extensive gangrene of the tongue, floor of mouth, and contiguous parts was found. Such accidents are calculated to interfere quite seriously with the popularity of the injection method.

The painfulness of the method will always be a great objection to its use with persons of sensitive skins.

As far as I was able to observe, the inunction method was the popular one in all the great clinics of Vienna and Paris; that of Professor Fournier possibly excepted. Professor Fournier preferred the administration of mercuric protiodide by the mouth in the great majority of cases. In cases of syphilitic iritis, Galizowski always immediately prescribed mercurial inunctions.

Farther on in his communication, Dr. Wells speaks of palmar psoriasis. I judge that he means syphilis affecting the palm; but why not say palmar syphilis? why use a name belonging to another well-defined disease? If the physician cannot make the differential diagnosis between syphilis and psoriasis the appellation syphilitic psoriasis may prove exceedingly handy. He can treat for syphilis and failing to cure, resort to treatment for psoriasis, and when he at last ascertains what disease he has had on hand, triumphantly exclaim: "I told you so."

E. WETZEL, M.D.

DENVER, COL.

AN UNNAMED FEVER OF THE SOUTH.

To the Editor of the Medical Record.

SIR: In the MEDICAL RECORD, of May 30th, is an article by Dr. T. R. Evans, entitled: "Is the Contagion of Typhus Fever always Imported?" He describes fifty-two cases of continued fever, treated by himself at a mining village in Western Virginia, and takes the view that they were cases of typhus generated spontaneously in that locality. I have no doubt of the fact that the fever observed by him is the same as that seen very extensively in many portions of the country, particularly in the more Southern States.

My reason for writing now is to take exception to his diagnosis, and to call attention to what I believe is the

producing cause of the fever in a large proportion of cases.

In a lengthy discussion of the subject, several years ago, in the Birmingham, Ala., Medical Society, there seemed to be an equal division of opinion as to its being of typhoid or malarial origin.

It was my fortune to treat nearly three hundred cases of this fever at a mining settlement in Alabama, where my opportunity for studying its character was excellent. In none of those cases did I see indications which led me to believe that they were produced by the poison of either typhoid, typhus, or malaria. There was no delirium, except in a limited number of cases, and then only for a few hours, when the fever was at its highest.

Constipation was the rule, and the intestinal symptoms of typhoid were never present, with the exception of hemorrhage in two cases. Epistaxis was present in but two cases. The eruption of typhoid or typhus was never observed, although sought for in many cases. One point alone would exclude either of those fevers, and that was the termination, every case ending in complete recovery, except one, which was accompanied by glaucoma, and the loss of one eye.

The houses were built of rough plank, were unceiled, and had full ventilation through the many cracks in the walls and floor. Overcrowding was not usually found. Malaria was excluded by the regular continuancy of the fever, and the total absence of results from the use of quinine.

The fever usually made its appearance gradually, and went off in the same manner, the evening temperature being as a rule the highest. The duration was from two days to six weeks. The temperature ranged from 100° to 103° F. in the milder cases, to 106⅕° F. in the most severe.

I have stated what it is not, without being able to say just what it is.

Typho-malaria is a misnomer, so far as this fever is concerned. I have found no description of it in the standard works, but have read discussions of it in the proceedings of the various Southern medical societies, and have seen several articles in reference to it in the medical periodicals, mostly from men residing in the South.

Cause: Anything which weakens or exhausts the system will be a predisposing cause. Thus, I have seen it follow immediately a fatiguing railroad and carriage ride. One case accompanied continued vomiting of pregnancy, and saw its regular course, although the vomiting ceased in the beginning of the fever. Overwork, mental anxiety, and insufficient or improper food are other causes. I believe, however, that in the large majority of cases, the direct cause is the use of impure drinking-water.

By impure water I do not mean necessarily such as is contaminated by germs of the disease, if such exist, or even water rendered foul by the presence of sewage or other animal matter, but water containing a too large percentage of organic vegetable matter. Such water usually proceeds from springs and wells located in woods, or where leaves and other vegetable substances are allowed to decay, and the sewage therefrom to find its way into the sources of the water supply.

At the mining town in which I was located the population was supplied principally with water from three wells and six or seven springs, the latter mostly flowing only in wet weather. One of the wells, which supplied fifteen or twenty families, was in the centre of an old field containing no trees or shrubbery of any kind. Although quite shallow, the water sometimes approaching the surface near enough to be reached by hand, there was but little opportunity for contamination. Not one case of fever occurred in any family using water from that well. Of the other two one was dug on a hillside in the wood with a small growth of trees above it. It however went several feet into the rock and most of the surface drainage was carried off. A number of the roots of trees were cut in the digging, their ends projecting into the well. Leaves could also fall freely into it. Of the families using from that, only two or three cases of fever in a mild form, each lasting only three or four days, were met.

The third well, two or three hundred yards distant, was in the bottom of a depression running through the woods, and received freely the surface drainage from all sides. Much clearing had been done around it and the tops, leaves, roots, and stumps, were allowed to remain on and in the ground. The water was still further contaminated by the habit the children had of throwing various substances into the well. Of the twenty or more families using from it, not one escaped, and there was rarely a time when one or more cases of fever could not be found in each house, as long as the people continued to use from the well. Rough testing with permanganate of potash showed the water to be foul. The second was much less so, and the first scarcely at all. As soon as the use of the water was suspended, the fever began to abate. One family, however, continued to use it to some extent, and continued to have fever.

As the summer advanced, and the springs began to run low and the process of decomposition to advance, families using therefrom began, around first one and then another of the springs, to have fever, until finally all but one, having been tested, were condemned. The purest water of all was obtained from the interior of the coal mine itself.

The writer, the young men who conducted the store and office, and several families who used water from the mine, escaped fever altogether, though living only a stone-throw from the centre of the fever district, around well number three. There was, however, one exception, as I at first supposed. One of the store-men was taken sick with the fever, and upon investigation it was found that the porter had been in the habit of carrying water for him from one of the condemned springs, instead of the mine.

I observed the same fact as related by Dr. Evans, that the men were much less liable to fever than their families. I attributed that to the fact that they were in the mine during the greater part of the day, and used the water there, while their families used what came from wells and springs. The fever prevailed almost entirely during the summer and fall, and could not have been due to crowding and imperfect ventilation.

Since returning to this locality I have met during the summer and fall a number of cases of the same fever, and have found that the water supply in such cases, this being a new town, has been from springs similar to those described. One family living several miles from here, under the care of another physician, had fever continuously for several months during the fall and winter. In passing I observed that the spring came from beneath the site of a deserted saw-mill, and a large mass of decaying sawdust was getting in its work. I have been told by a missionary from Japan that they never dare drink the water there without first boiling and then filtering, or fever would be the result. He attributed it, however, to the amount of human excrement used as manure, but could not give a description of the fever.

I have called attention at other times to drinking-water as a cause of the fever, but have seen no special reference made to it by others, in the reports of discussions, etc., which I have read and heard. In the Blue Grass region of Kentucky this fever is unknown, and I suppose the same is true of a large portion of the North and West, where the land is under a high state of cultivation, and the same causes do not prevail, although crowding and poor ventilation must be more common than in the South.

In the South, however, we find large forests and masses of decaying vegetable matter to contaminate the water, and in consequence one-half of the practice of many physicians is in treating this anomalous fever.

Will others take this idea up, and make more thorough chemical and microscopical researches along the same line, than I have had the opportunity of doing? Cannot someone also give it a name sufficiently descriptive, to justify its universal acceptance, and thus prevent its sail-

ing under the false colors of typhoid-malaria, typho malaria, bilious, typhus, etc.? The treatment should be mainly preventive, as indicated above. Look well to the source of the water supply. As to the medical treatment, the arseniate or sulphate of strychnine is useful in the beginning. Antipyretics during the attack, cold water sponging, acetanilid, antipyrin, etc. Mineral and vegetable acids are useful and grateful. Tonics of iron, quinine, strychnine, and phosphoric acid at the close. Occasional laxatives, of which calomel seems the best, are indicated.

Alcohol was given to none of my patients, and I have not yet met a case in which I thought it indicated. All cases recovered, under any or no treatment, except absolute rest in bed and proper diet, which must in all cases be insisted upon. Quinine is not only useless, except as a tonic, but renders the patient more uncomfortable if given in full doses.

GLASGOW, VA., June 9, 1891.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 5, 1891, to July 11, 1891.

IRWIN, BERNARD J. D., Surgeon. Relieved from duty at St. Louis, Mo., and ordered to Chicago, Ill., for duty as Medical Director, Department of the Missouri.

BANISTER, W. B., Assistant Surgeon. Granted leave of absence for fourteen days.

BUELL, JAMES W., Assistant Surgeon. Is retired from active service, by reason of disability incident to the service.

OWEN, WILLIAM O., JR., Assistant Surgeon. Detailed to attend the encampment of the Illinois National Guard, near Springfield, Ill., from July 18 to 25, and August 11 to 18, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 11, 1891.

BOYD, ROBERT, Assistant Surgeon. Ordered to the Dale, Washington, D. C.

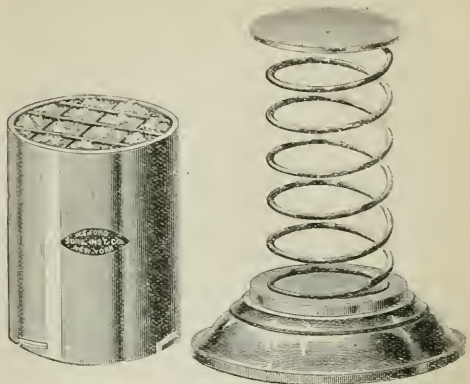
New Instruments.

AN ECONOMICAL COTTON RESERVOIR.[1]

BY WENDELL C. PHILLIPS, M.D.,

ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT.

THIS reservoir is a labor-saving and convenient device for office and dispensary use. The base is solid and of sufficient weight to hold the reservoir down while cotton is being withdrawn from any one of the spaces at the top. To the base a strong wire coil spring, surmounted by a flat metal plate, is attached. The remaining section is simply a metal cylinder, divided at the top into spaces, through which any amount of cotton desired can be drawn. At the lower end of the cylinder are grooves which catch upon pins at the base and hold it in position. When using this appliance the probe or applicator can be retained between the thumb and forefinger of the right hand ready for use, while with the left hand the exact amount of cotton required can be withdrawn and applied directly to the probe, thus saving fully one-half of the time required when the mass of cotton is held in the left hand or an ordinary receptacle, which necessitates the use of both hands.



By the use of this appliance the cotton is kept clean and none is wasted, which will be especially appreciated in hospital and dispensary practice, where there is always so much waste in materials of this kind.

Since this cup was made I have arranged to have covers made to keep the dirt and dust out when not in use.

The appliance was made for me by Mr. Ford, of the W. F. Ford Surgical Instrument Co., New York.

SOME PRACTICAL SUGGESTIONS FOR DEEP URETHRAL MEDICATION IN THE TREATMENT OF POSTERIOR URETHRAL CATARRH.[1]

BY E. L. KEYES, M.D.,

NEW YORK.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY: When I was asked to add my voice to the entertainment which the Section I help to represent is expected to afford you to-night, I cast about me for a subject which, while as free from technicality as possible, might yet be far-reaching enough to interest the greater number, and at the same time probably provoke from the fellow-members of my Section a discussion profitable for all.

I have been unable to select one which seemed to me more appropriate than the one I have chosen. For posterior urethritis has become of late years a malady very well recognized by those who deal closely and often with genito-urinary cases, and its management is much simpler than what it was a few years ago; yet there exists in the profession at large, seemingly, a lamentable ignorance about it, which leads to much misconception and a considerable amount of mismanagement of cases, the diagnosis of which is very easy and the treatment of which may be successfully carried out by anyone in many instances without calling for expert skill in the use of instruments. I have certain ideas on these subjects, ideas which have brought me to the satisfactory conduct of some very stubborn cases, and if a display of these in a general assembly like the present can lead the mind of anyone, until now unaccustomed to make distinctions, to a little more thoughtfulness and the exercise of something like logic in the diagnosis of gleet, and in that way to a more general application of reasonable therapeutics, I shall feel repaid for whatever effort this paper may cost me.

A gleet, as we all know, is not a disease. It is simply a symptom of some morbid condition, the nature of which it should be the function of the physician to determine; and it is as irrational to prescribe for a gleet, in any hope of curing the malady which occasions it, as it is to prescribe for cough with the same end in view without first by physical examination endeavoring to ascertain the source from which the symptom derives; yet my experience leads me to believe that in the profession at large the opposite course obtains, and that a gleet is treated in a routine way by the vast majority of practitioners, either by injections and internal medicine, or by sounds, or internal urethrotomy, or all, according to the imagination of the prescriber, which leads him to generalize as to the causes of gleet and the methods of curing it.

This generalization is based upon the very undeniable efficacy of injections in most gleety conditions, and upon the wide-spread and very proper belief that one of the most constant symptoms of urethral stricture is gleet.

Such a generalization would be not unprofitable in a therapeutic sense if anyone were in a position to say exactly what stricture is; but the modern doctrine of stricture of large calibre has rendered this well nigh an impossibility, for every natural undulation of the canal may be so classed by the physician who is properly impregnated with the large calibred stricture idea, and he is sure to find what he looks for in every case of gleet.

And so it turns out in many and very many an instance. When a patient with a gleet seeks advice, his physician has no thought of, perhaps little knowledge of, the possibilities and the prevalence of posterior urethritis; he neglects to make the very simple tests by which posterior urethritis may be demonstrated, and he first injects his patient and dilates or cuts his urethra, on the stricture theory—often to the considerable detriment of his patient, who finds himself after the treatment with his gleet still persisting, and the added discomfort of a wide-mouthed dribbling urethra, which never clears itself entirely after the urinary act, or possibly a permanent deviation of the penis from the correct line during erection (as a result of over-cutting), or a relapsing epididymitis or permanently irritable bladder from the injudicious use of very large sounds.

I make this general criticism not as directed against any urethral therapeutic measure, or any school of thought in urethral pathology. I personally believe in, advocate, and practise the cutting of anterior (and some posterior) strictures, of large as well as small calibre, when, but only when, they can be demonstrated to be the cause of the gleet which is to be overcome. My criticism is directed against the indiscriminate employment of a method, most useful when appropriate, and against the frequent neglect of such a study of the case as would lead in many instances to a direct localization of the cause of the gleet in the posterior urethra, and thus save the patient unnecessary mutilation, and the general body of the profession many animadversions from the laity.

I speak of what I do know, and can state honestly that the vast majority of cases of chronic gleet which come to me or are referred to me for advice, have already been cut anteriorly in the urethra from one to eleven times, and that very few of them have ever been tested by their attendants, or any effort made to ascertain whether they had posterior urethritis or not.

Such a state of affairs is not professionally creditable, and although neither I nor anyone (in my opinion and belief) can tell you how to cure every case of posterior urethritis, still one may easily learn how to cure many, and diagnosticate all cases, and at least may know what he is treating and how to direct his fire against it, rather than to take a random shot into the bushes in the hope of bringing down some game, because, forsooth, some feathers are seen on the boughs.

Gleet is really an insignificant matter (unless still virulent, a point I do not care to touch upon in this paper), and if a like amount of mucus or muco-pus escaped daily from a man's nose, or mouth, or anus, or even his ears or eyes, it would generally discomfort him not at all, or certainly much less than it does when he sees it exuding or milks it out of his urethral canal. Gleet must be classed with the little miseries of life, like shirt-buttons, and corns, a mother-in-law, a wrinkled stocking, a cross in hopeless love; yet philosophers have discovered that it is the sum of these little miseries that make up the real woes of life, and there are few of us who have not seen a very sensible man driven nearly to the verge of desperation and despair by the very insignificant torture of a protracted urethral discharge; therefore it is worthy of consideration, and any means tending to modify it is deserving of respectful contemplation.

The morbid conditions capable of producing a gleet are very many, so many that I shall not weary you by

[1] Read before the New York Academy of Medicine, May 21, 1891.

enumerating them here, since it is my intention to deal only with that variety dependent upon posterior urethral catarrh. I need only say that when a gleet is due to anterior urethral catarrh, caused by stricture, granulations, or what not, the source of the pus may be demonstrated without the endoscope by gentle, thorough, hot irrigation of the anterior urethra by means of a soft catheter passed into the sinus of the bulb, and the immediate subsequent use of the simple metallic bulbous bougie, provided the meatus be reasonably large; for if the pus comes from granular or strictured portions of the pendulous urethra, the irrigation will only wash away what lies loose in the canal, and the bulb will subsequently bring forth upon its shoulder soft muco-purulent clots generally tinged with blood, which have been scraped off the excoriated areas from around which the inflamed mucous membrane secretes whatever free pus exists. There may be tight areas which the bulb will detect, but if there be not a granulating surface upon the tight area or behind it which the bloody muco purulent clots on the shoulder of the bulb will demonstrate, or their absence disprove, then the cutting of such tight areas will not, in my opinion, favorably modify a given gleet in most instances. Yet, even allowing that there be some tightish areas, and even granting that they be moderately granular, still, if there be posterior urethritis the cutting of the tight areas, although it may greatly moderate, will not cure the gleet, and the patient should be so informed before any cutting operation is undertaken; or he is quite sure to be disappointed, and often to misjudge the physician who has been zealously working for his relief.

Therefore, again, it is desirable to recognize the existence of posterior urethritis, even when it is associated—as is often the case—with coincident anterior urethral catarrh; and the manner of doing this is so simple that it is surely worthy of being put on trial. Indeed, this diagnostic method is so well and so generally known that I almost hesitate to present it before a body of gentlemen so well equipped in general knowledge as the members of this Academy certainly are; yet its constant neglect in good hands emboldens me and fortifies me in reiterating it with emphasis before you.

When there is posterior urethritis, from whatever cause, the quantity of pus lying in the urethra behind the bulbo-membranous junction is disproportionately great when compared with the amount of gleety discharge that appears at the meatus. This may be easily demonstrated.

When pus forms in front of the triangular ligament, it readily and promptly, for the most part, favored by gravity and the fact that the urethral walls lie in contact with each other, reaches the meatus. When it forms behind the bulbo-membranous junction it more readily takes the opposite course, flowing backward into the prostatic sinus and into the bladder.

When, therefore, a case of gleet is examined, if the urethra be milked by firm pressure with the finger, from the perineum forward, until all the pus that will come be squeezed out and then the patient be instructed to urinate in two parts, into separate glasses, if he have even moderate posterior urethritis the quantity of pus mixed with the first urinary gush, representing the washing out of the deep urethra, will be disproportionately great when compared with what has flowed out spontaneously from the meatus or been milked out by the physician before the urinary act, as shown by gross inspection of the specimen. And if the grade of posterior urethritis be intense, not only will the first uriuary gush be purulent, but also the entire second urinary flow will be turbid with pus. In case of doubt the anterior urethra may be irrigated before the urinary test in two flows is applied.

The one obvious source of error here is a focus of suppuration in the substance of the prostate, in a seminal vesicle, in the bladder, or in the kidney.

The differentiation of these sources of purulent flow opens up a field rather too wide to be critically considered in a paper of the limited length my time affords. Suffice it to say that prostatic and seminal vesicular suppuration may usually be demonstrated by a milking of the prostate and seminal vesicles by a finger in the rectum, between the first and second urinary flows, a portion of urine being retained in the bladder to be ejected in a third urinary flow and the specimens examined microscopically after settling.

Bladder and kidney suppurations, although they may occur in company with both anterior and posterior urethritis, and will of course render all the urinary specimens turbid with pus, are beyond the scope of this paper and need not be considered.

The commonest kind of posterior urethral catarrh, ordinarily following a protracted gonorrhœa, is the one upon which I prefer to concentrate my and your attention.

Its clinical picture is this: A patient has gonorrhœa following a more or less protracted course, perhaps complicated toward the end with swelled testicle or a more or less pronounced attack of gonorrhœal cystitis or vesical irritability, and then subsiding into a condition of mild gleet. Such a patient procures some, as he conceives, suitable injection, and as long as he continues to use it once or twice a day his urethra remains apparently dry, and he considers himself well. Within a day or two, however, after leaving off his favorite injection the discharge reappears and goes on to reach a certain grade of intensity, possibly without other symptoms, or perhaps accompanied by itching or discomforting sensations in the anterior urethra near the meatus, or referred to the perineum, and sometimes accompanied by a little urinary urgency and precipitancy. Such a man, even while keeping down his show of gleet by means of injection, will notice that if he drinks wine or spirits, or if he indulges in sexual intercourse, especially to excess, or even if he has a nocturnal emission, that his show of gleet will certainly become promptly aggravated. These are the cases that get a new gonorrhœa every few months, and those who claim to have acquired a new discharge from perfectly healthy women—and their number in the community is considerable.

They are cases of posterior urethritis often pure and simple. They fly from one nostrum to another, and from one physician to another. Sooner or later all of them have the anterior urethra widely cut for alleged stricture of large calibre, and some of them by this means receive temporary, others permanent, benefit—when the membranous urethra is the seat of soft stricture which keeps up the posterior urethritis in their particular cases, and when the deep urethra will tolerate the passage of sounds without resenting the traumatic violence thereby inflicted.

But this factor of deep urethra tolerance to sounds does not by any means always exist, and the sequel to the cutting and the passage through the deep urethra of large dilating instruments is quite often an aggravation of the discharge and a lighting up either of mild cystitis, prostatitis, or epididymitis.

This picture is surely a familiar one to many of you.

Take such a patient at his best, between his acuter attacks, when he thinks that he is keeping himself well, as he calls it, by the use of an injection, and when he has no visible show of gleet—and ask him to urinate in a glass. Floating about in the urine will be noticed cottony chunks and irregular masses of fleecy muco-pus (not simple compact linear shreds), and more or less free pus. This patient is playing the ostrich rôle, and ignorantly imagining that because he sees nothing there is nothing to see, when all the while the drops of pus are oozing backward in his urethra and being washed out by each urinary act—drops which, if they did come forward and show at his meatus, would convince him that his injection was a snare, and only a mask to conceal the presence of the enemy.

If one of these little fluffy, cottony chunks that float about in the urine be caught up in a pipette and examined microscopically, it will be found to be made up of more or less closely arranged rows or layers of pus-cells,

strung out in striated films of colloidal prostatic mucus, entrapping the larger oval and rounded succulent cells from the neck of the bladder, some granular bodies, occasionally a crystal of oxalate of lime or uric acid, occasionally a stray spermatic element or a sympexion, sometimes a perfect hyaline prostatic cast—a cast to deceive even the elect, especially when, as is often the case in patients showing prostatic casts, particularly if there be also spermatozoa, the urine contains a faint trace of albumin.

A case like the typical one I have just described is often posterior urethritis pure and simple; there may be a small meatus and points of physiological anterior narrowing, but often the posterior urethra is alone at fault and is responsible for the relapsing attacks of urethritis, and for the mild persistent gleet.

The sceptical among you may well ask at this point, if this be a case of pure posterior urethritis, why does any of the discharge at all show at the meatus, and why does an injection, which does not reach the alleged diseased area behind the triangular ligament, so positively moderate or even control the anterior discharge, at least in so far as causing it to cease to appear at the meatus is concerned. The explanation is easy.

Although the focus of disease is posterior to the bulbo-membranous junction, yet the congestion extends forward along the mucous membrane into the sinus of the bulbous urethra, and from this point a moderate oozing of pus occurs—as well as, to a very moderate extent, from the true focus of disease behind the bulbo-membranous junction. Now, the injection reaches and acts as an astringent upon the turgid vessels in the bulbous sinus, and the astringent exerts itself along the continuity of mucous-membranous surface to a moderate extent into the membranous urethra and beyond the bulbo-membranous junction, and a repetition of the injection by a continuance of astringent action keeps down the discharge without reaching or curing the actual focus of disease itself; for if the anterior injection be too strong or be forcibly crowded back too far, cystitis or swelled testicle is, as is well known, a not uncommon result.

That a local application, acting simply upon the livid congested membrane in the sinus of the bulb, may control a gleet without curing it can be often demonstrated by touching this livid membrane carefully with an astringent through an endoscopic tube; and that an application made on one side the bulbo-membranous junction extends its influence more or less to the other side may be also demonstrated by making a membranous urethral instillation of nitrate of silver, ever so carefully, and then inspecting the mucous membrane of the bulb, anterior to the triangular ligament, through an endoscopic tube. This spot, before of a more or less livid red, shows the pale white staining of the nitrate of silver solution. This fact was first observed and pointed out to me by Dr. James P. Tuttle; the only possible criticism upon its accuracy is that a minute portion of the silver solution has followed the injecting instrument on its withdrawal, in spite of all precautions taken.

But my subject drags. I came here to make some practical suggestions to cure posterior urethritis, and must hasten to that point. My suggestions are certain substances to be injected into the seat and focus of the disease with the deep urethral syringe. The method is not new, some of the substances are not ordinarily in use.

I do not at all claim that posterior urethritis must be treated locally to get well. On the contrary, most cases ultimately get well, and they do so without local treatment. Rest, the balsams and alkalies, the demulcent drinks, counter-irritation, time, change of air, sea trips, treating the anterior urethra, iron in chronic cases—all these things are potential, and most of them can be happily combined with the local posterior treatment, to the great advantage of the latter, and their co-operation is sometimes essential to the rapid and perfect effectiveness of the posterior treatment. I do claim, however, that most cases are suitable for local direct treatment, and that such cases under suitable local applications improve with a rapidity which is gratifying to the physician, and quite obvious to the patient; and I claim further that by recognizing the malady and treating it locally, many a urethra may be spared the use of the knife, and very much time saved.

Finally, I state candidly that a few cases are positively unsuited to local treatment, and get worse under it, no matter what substance is injected. To this class belong most tubercular cases and some simple inflammatory, and some ordinary gonorrhœal cases. When, however, the treatment disagrees, the symptoms (notably the discharge of pus) become so promptly and so obviously aggravated, that the futility of repeating the application becomes at once clear, while very little time is lost in making the test. I may add finally, that there is practically no danger of producing cystitis or epididymitis, if the instrument be used carefully, and not inserted too far. The risk of occasioning these complications is vastly less, according to my experience and belief, than that incurred by treating the malady with anterior injections or with sounds—or indeed less than is the risk of these complications if it is left untreated locally, and internal medication be relied upon.

The instrument I employ is the syringe that bears my name. It is founded upon Ulzman's model, and is superior to the latter in being made in one piece, so that no injection soils the fingers, and in being more solid. Guyon's syringe has a bulb at its extremity and injects backward. It must, therefore, be introduced through the inflamed area to be effective, a manœuvre which inflicts unnecessary mechanical violence upon the tender parts. The same objection obtains in the case of all syringes having lateral holes or slits. My syringe and that of Ulzman have only one minute opening at the tip. This tip need be inserted only just within the hole in the triangular ligament, just beyond the bulbo-membranous junction. So inserted, the membranous urethra grasps the tip of the instrument and the contents of the syringe—twenty minims or more—may be gently thrown in, and the entire injection will quietly flow backward along the membranous urethra, through the prostate, and into the bladder, with as little violence as possible, not one drop escaping at the meatus upon the withdrawal of the syringe. The little air sucked up into the syringe upon charging it may be disregarded, as it remains at the top of the instrument and in its tube, and need not be discharged into the urethra.

Formerly, in using strong injections I deemed it important to throw in only a very few drops at the diseased focus. Now I endeavor to produce my result by using much milder injections than formerly, and I throw in the entire contents of the syringe in every instance, except where nitrate of silver is used in a strength greater than ten grains to the ounce, when I use a few drops only. I increase the strength of injection of a given substance only gradually, after establishing a tolerance of the milder strength, and in this way I avoid irritation, formerly more common. When the source of the flow of pus is reasonably well forward in the membranous urethra, I generally make the injection before the patient urinates. When the inflammation extends farther backward and the supply of pus is considerable, I cause the patient to urinate just before making the injection, so that the injected fluid may flow into the bladder and become applied thoroughly to the mucous membrane at the internal prostatic urethral orifice, without being there diluted or neutralized by coming into contact with urine in the bladder at this point.

In suitable cases the free pus first disappears from the second urinary flow (the urine being voided in two parts), then it disappears entirely from the urine, some shreds still remaining. These are attacked by increasing the strength of the injected fluid, or, if there be some stricture in the membranous urethra, by the safe use of sounds after the catarrhal surface has been modified by the previous use of

the injections, combined often with anterior astringent injections, which the patient administers himself.

I have employed in deep urethral injection most of the substances which have repute in controlling the flow of pus from mucous membranes, even Pond's Extract. Such substances as hydrastin, boro-glyceride, nearly all the lead and zinc salts, iodoform, creolin, pyoktanin, etc.; but at the present writing I have come to rely almost exclusively upon four substances—the sulphate of thallin, the glycerole of tannin, the sulphate of copper, and the nitrate of silver. I never now make a preparatory injection of cocaine, as I consider it unnecessary, often harmful.

The Sulphate of Thallin.—This I consider a very valuable drug. Its chemical name is tetrahydrotarachinanisol. It was introduced into anterior urethral medication as an ordinary injection, with words of high praise, by Goll, of Zurich, about five years ago, and since that time has constantly appeared as one of the ingredients of the antrophore, an instrument of torture, when employed in the deep urethra, which I only mention to protest against. I am not aware that anyone else has employed it in solution for deep urethral medication. I have so used it for about four years, and always with increasing frequency and confidence. It is bland and practically unirritating, and may be used up to a saturated solution, which is about twenty-four per cent. It is suitable for all the acuter forms of inflammation (except in cases of acute frank, recent gonorrhœal cystitis, in which the nitrate of silver has the preference), and it is the substance I almost invariably commence with in a solution in water of about three per cent., increasing at each injection up to six, nine, and twelve per cent. The last-named strength will usually do all that thallin can do in reducing the show of free pus in the first urinary rush. The intervals of making this mild injection are best spaced by two, three, or four days, according to the effect, which is sometimes wonderfully prompt and gratifying. The injection causes practically no discomfort, only a little warmth as a rule, and may be retained as long as the patient chooses.

The Sulphate of Copper.—This substance I use in a ten per cent. solution in pure glycerine. This I dilute with water for use, commencing at about one grain to the ounce and working up rather rapidly, if it agrees and has a good effect, to the full forty-eight grains in the ounce. It is markedly astringent in suitable cases, and generally in weak solutions, pains but little more than thallin; very strong solutions, however, of course feel hot and cause precipitate and moderately painful urination for perhaps several hours. The stronger the solution, the longer the interval before a second application is advisable. I do not very often go above a strength of ten grains to the ounce.

The Glycerole of Tannin.—This substance, pure, is too thick to be sucked up into the syringe easily. I use it reduced by adding water, seventy five, fifty, or twenty-five parts, where a more astringent (but sometimes less irritative) influence is aimed at than that procured by the copper solution.

The Nitrate of Silver.—I employ this remedy as high as a ten per cent. solution, but very, very rarely—practically never in catarrhal cases—use anything like this strength. It is most useful in acute gonorrhœal cystitis, and as a final astringent when copper and tannin are not efficient. I dilute it with water at each time of application, commence usually at a strength of one grain to the ounce, and very rarely have to go beyond ten, making the applications every three to eight days—studying the effect and being guided by it. This is the harshest of the applications, causes the most pain, precipitancy, and urgency of urination (which often lasts several hours), but frequently renders incalculable service. Carefully used, it is free from the danger of producing complications.

By the careful and observant use of these four solutions, which anyone may easily master after a few trials, the greatest advantage may be obtained in suitable cases of posterior urethritis. Did I not have them at my command, I think I should give up the treatment of gleet. When they disagree the fact is immediately obvious, and their good effect equally clear when they suit a given case, while their employment is generally progressively satisfactory. The thallin makes a black solution when used in the same syringe with the nitrate of silver, which it takes some time to wash out. I therefore use two syringes, one for thallin and tannin, the other for copper and silver.

1 Park Avenue, May 21, 1891.

A CASE OF GASTROSTOMY (HACKER'S METHOD) FOR IMPASSABLE STRICTURE OF THE CARDIAC END OF THE ŒSOPHAGUS.

Recovery—Subsequent Dilatation of the Stricture.[1]

By ROBERT F. WEIR, M.D.,

Attending Surgeon, New York Hospital, etc.

The patient, aged fifty-nine, whom I exhibit to the Society this evening, had been in fairly good health, with only slight disturbance in his digestive organs, until the beginning of 1890, when in one day he had two severe hemorrhages, with vomiting of blackened blood from the mouth, though no discharges of changed fæces were noticed. This was considered at first to be due to a contracted liver, but repeated examination of that organ failed, at a later date, to detect any change in its size. After this attack he was troubled, more or less, by irregularities in his gastric and intestinal functions. He had another sharp hemorrhage in June last. In August the first symptoms of interference with deglutition presented themselves, associated with vomiting. For this the introduction of an ordinary stomach-tube was resorted to daily to wash out the stomach. This relieved the nausea and retching, and he continued free from pain until the middle of September, when the use of the stomach-tube became difficult, and thereafter it could only be occasionally employed. The hindrance in swallowing also became more noticeable, and was joined at times with regurgitation of the food. I was called to the patient about November 1st, by the physician then in attendance, Dr. J. J. Henna, who had recognized the presence of an increasing stenosis. I failed to get even the finest œsophageal bougie into the stomach, the arrest being found with all, as with the *bougie à boule*, No. 20 French, which was first introduced, at seventeen inches from the incisor teeth. The resistance to the onward progress of the bulb was a firm one and was without pain, nor did any blood or pus appear at any time, either before or after the repeated efforts that I made, with due intervals, in the two weeks following my first examination. He was still able to swallow with some effort, and with great slowness and circumspection, a moderate quantity of milk, and this, with some grape-juice, which he liked, served with rectal enemata to keep up fairly his strength, though he was then losing flesh. My judgment at the time was that his stricture was probably due to a neoplasm, and that it was situated near the cardiac end of the œsophagus, and I advised that unless success crowned speedily the efforts to carry a dilating bougie through the stricture, that gastrostomy be done at an early date. His interest in political matters, for that was his *métier*, impelled him, with other considerations, to decline then my further attendance, and I did not see him again until December 13th. He had, however, in the meanwhile, been seen by several other surgeons, who, like myself, failed to pass in a bougie. Once also electrolysis of the stricture was tried. His condition now was materially changed. Little or nothing of food (milk and wine) passed into the stomach. Nutrient enemata (Rudisch's prepared meats) had been administered for nearly eight weeks, several times a day, and

1 Communicated at a meeting of the Practitioners' Society, held May 1, 1891.

his strength had failed so that he was now compelled to stay in bed and had wasted to ninety-eight pounds in weight, having weighed in January, 1890—before his first hemorrhage—one hundred and ninety-nine pounds. His loss during the last week was five pounds. Gastrostomy was now a necessity. Dr. Kinnicutt, who joined me in the investigation of the case, corroborated the excellence of the patient's kidneys, heart, stomach, and liver, and ventured the diagnosis of a fibrous or cicatricial stenosis. This, from his age and the absence of history of an ulceration of a size to produce such a contraction as here existed, I was only willing to admit after time sufficient had elapsed to sufficiently exclude carcinoma, to pronounce positively on this point.

It only remained, the patient having consented to submit to the operation, to consider the situation of the abdominal wound and the size of the gastric opening that should be selected to meet the exigencies of the case. The opening in the abdominal wall should, it seemed to me, be placed where, if possible, the leakage of the gastric opening might easily be controlled. The usual incision (called Fluger's) on the left side along the free border of the costal cartilage, as the latter rises up to the ensiform cartilage, has been sufficiently proven to be without any advantage in controlling the egress of the contents of the stomach after a successful gastrostomy.[1] This region only allows of a ready access to the stomach. Did other methods offer anything better? That proposed by Hahn,[2] of Berlin, of making the gastric opening in the space between the ninth and tenth left costal cartilages, at a point as far forward as possible, seemed at first more suitable. The evidence presented by its author, in some eight cases with but one death, and those reported by von Hacker and others, showed that in this situation, by the elevation of the stomach kept up by the unyielding cartilages and by the narrowness of the space itself, little or no escape of the irritating gastric juice or of the stomach contents was to be expected. Moreover, the mortality of the operation was comparatively slight. Indeed, concerning this I may here say that, under antiseptic precautions and improved technique, the mortality of gastrostomy has materially diminished. This has also been brought about by the earlier resort to the operation—in other words, when the patient is in better condition. In fact, to finish the last point, the old dictum that gastrostomy should not be performed so long as food can be got by ordinary deglutition into the stomach, is not to be considered as correct in surgery, but rather that it should be resorted to as soon as one is convinced that the patient is beginning to be starved, and it is proved that this is not to be obviated by permanent tubage, as in carcinomatous strictures, or by dilatation or otherwise, as in stenosis from other sources. But to return to the consideration of Hahn's procedure: it was liable to two objections, one common to all gastric openings in this site, that is, that necrosis of the cartilage with its concurrent suppuration-ulceration, and pain not infrequently takes place, as is proven by cases of Dalton, Hacker, and Hahn himself; and the other, of much possible importance in my patient's case, that it forbade any large opening into the stomach, should this be needed either at the time of the operation or subsequently. I therefore abandoned this plan of operation and turned to that proposed by von Hacker, one of Billroth's assistants. This was to make the section of the walls of the abdomen within the limits of the left rectus muscle, some three inches below the ensiform cartilage. By tearing or pulling through the longitudinal fibres of the muscle after division of the skin and fascia, one could come readily down to the peritoneum, and, after its section, to the stomach; this organ could then, after being duly sutured, be openen either immedtately or after the lapse of a few days. Its opening would then in this situation be encircled as it were, or literally pressed on each side by the longtitudinal fibres of the rectus which would act thus as a kind of sphincter. Hacker presented[1] a report of a series of twelve cases similarly treated, with the satisfactory result of not a single death from the operation itself, but with the specially noted point that little or no leakage of the abdominal contents took place. To meet the few cases where this did occur he, or rather one of his aids, Dr. Max Scheimpflug, contrived the rubber balloon-cannula which is now shown in Fig. 1. It

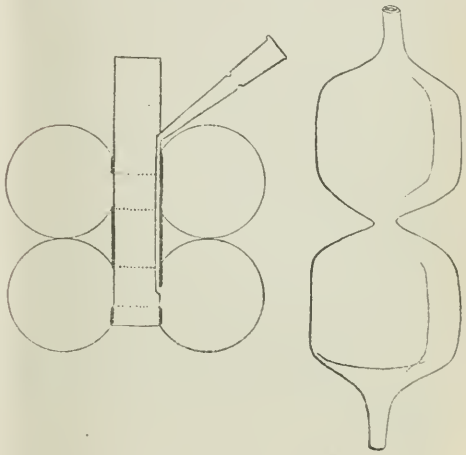

Fig. 1.—Diagram of Scheimpflug's Balloon-cannula for Gastrostomy.[2]

is introduced empty and then inflated. Its interior pressure occludes gently the gastric opening. This method of Hacker's allows one, if occasion require it, to enlarge the opening in the stomach to any desired extent.

The possibility of a large incision was dwelt upon at some length, because of the chance of the present stenosis both being of a cicatricial character and of its situation at or near the cardiac orifice of the stomach, and finally, of its being insurmountable to the passage of bougies introduced by the mouth. I had to consider the needs of each probable case. It might be determined, for instance, on exploration made with the finger or hand after opening the peritoneal cavity outside the stomach, that the forcible dilatation applied so many times with success to the narrowed pyloric orifice could be employed at the cardiac end. Loreta has reported four successful stretchings of such situated stenoses. This would obviously require a large opening into the stomach. Or, perhaps the stricture under the anæsthetic might be penetrated either from above or from below, and by this or other similar means as a guide enlarged by cutting instruments, as from the abdominal wound upward. Lange did safely in one instance, and Bergmann and others have done by dilators, and the gastric and abdominal wounds either immediately or subsequently closed. All these conditions, it

[1] Terrier (Gastrostomie pour cancer de l'œsophage, Revue de Chirurgie, Avril, 1891), however, still prefers the old (Fluger's) incision along the ribs, and after making a small incision only introduces a tube for feeding purposes, at other times it is sedulously kept out of the wound. In this way no undue patulousness occurs and hence, he says, no leakage, and gives five cases supporting this claim.

[2] Hahn makes first an incision parallel to the edge of the left rib, opens the peritoneum, identifies from within the eighth intercostal space. Then from without he makes a second incision obliquely through the skin and muscle of this space, sufficient to admit a forceps by which the wound is sufficiently opened by stretching so that the forceps can seize the chosen part of the stomach, held up by the finger and thumb introduced through the first incision. This portion of the stomach is then drawn through the opening between the ribs and there fastened by a few stitches, to be opened preferably after a day or two. The incision below the ribs is closed by sutures. The diaphragm is not touched by this method of operation, as this muscle is at least two centimetres distant from this spot. The ribs act, says Hahn, as a valve, and the opening does not readily enlarge (Centralblatt f. Chirurg., No. 11, 1890). Hacker, however, found that very distressing erosion of the ribs occurred in the two cases in which he resorted to Hahn's method. A similar experience is reported by Dalton, of St. Louis.

[1] Wiener klin. Wochenschrift, Nos. 37 and 37, 1890.

[2] Ibid, No. 25, 1888, p. 518.

seemed to me, could be met in the choice of Hacker's method via the rectus muscle.

The operation we accordingly performed under chloroform and full antiseptic precaution, December 16, 1890, by an incision three and a half inches long, beginning one inch below the ensiform cartilage and the same distance to the left of the median line. As soon as the muscle was exposed its fibres were separated by a director [1] and held aside, and the fascia and peritoneum beneath divided nearly the whole length of the wound. The fore and middle fingers being inserted into the peritoneal cavity, came first on the colon; this being pushed downward, the stomach was seized and drawn out of the wound to a moderate extent. While held *in situ* by an assistant and with it stretched as a guide, the fingers were carried to the spine and thence toward its cardiac end. No tumor was there to be felt, though this is very frequently present in neoplasms originating in the lower end of the œsophagus. This, though somewhat encouraging me toward active interference, was more than counterbalanced by the debilitated condition of the patient, and the latter feature of the case induced me to limit the surgical procedure to the smallest degree possible; so I was content to draw out a small fold of the stomach just beyond the level of the skin, and after pinching it together to make certain that the whole thickness of the two walls of the organ were between the fingers, a headless gold pin was purposely thrust through them all so as to pierce the included mucous membrane. It will be remembered that Howe and others, using one or two pins as may be, endeavor in so doing to avoid encroaching on the cavity of the stomach. Here, besides affording support to the stomach in the wound, the pin is intended to be used as a guide and indicator when the final opening into the viscus is made. The ends of the pin rested across the wound on the skin. The peritoneal coat of the stomach was now stitched with sixteen interrupted stitches to the peritoneum, which had been previously united on each side by several sutures to the skin. The peritoneal edges left above and below were then sutured, as also were in turn the muscular, fascial, and skin layers (Fig. 2).[2] The opening in the stomach was intentionally deferred until adhesions should have formed. This, it was hoped, would be postponed for forty-eight or seventy-two hours. The line of sutures was covered with iodoform collodion and antiseptic bichloride dressings were applied.

December 17th.—The patient did well, complaining occasionally of sharp pain in the abdomen, without any vomiting. Relieved by morphine injections, ♏ x. Peptonized milk enemata, ℥ vj., and brandy, ℥ j., were given every six hours, with a long tube, after washing out the bowel with warm water. Pulse, 95; temperature, 100° F. Apollinaris water and beef-tea given occasionally by mouth to relieve dryness and thirst. They were usually regurgitated after a time.

December 19th.—On the third day, patient having grown decidedly weaker and thinner but without signs of inflammation, though being contented and at ease, it was decided to wait no longer, but to make the completion of the gastrostomy. At two o'clock, under cocaine injected into the stomach-wall, an incision down to the transverse needle was made with a tenotome, and as the mucous membrane was divided it was recognized by the contact with the needle that the interior of the stomach was without doubt reached. This is a point of some importance, as this opening is not in every case an easy one to make, and the value of the pin as a guide was fully established in this case. Two small vessels spurted, requiring clamping. The mucous membrane was seized, pulled out, and fastened in four places to the skin by silk sutures. A No. 16 English rubber catheter just fitted in the opening when it was completed. Iodoform collodion was liberally daubed all over and around sutures and along line of original incision: then iodoform gauze, over which a sheet of rubber with a hole in it through which the tube running into the stomach snugly passed, and then a sublimate dressing fastened by adhesive bands and a bandage, completed the dressing. After the occlusion four ounces of strong beef-tea was poured through the tube into the stomach by means of a funnel, and finally the tube itself was closed by a pinch-cock and secured by a thread to a piece of sticking plaster to prevent its egress. This feeding was repeated every six hours in increasing amounts and of varying substances.

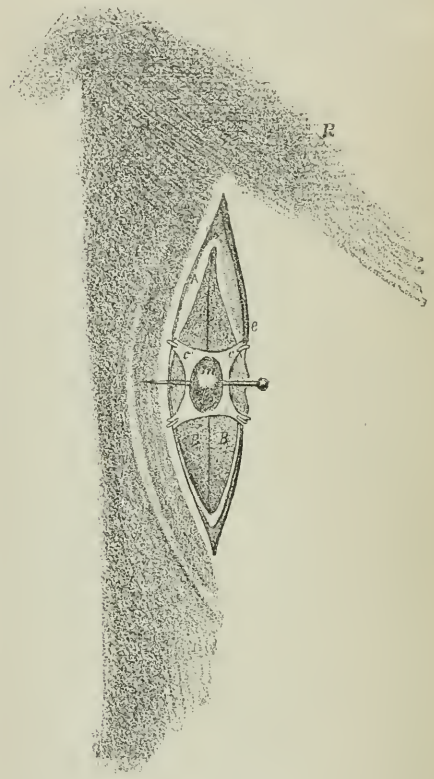

FIG. 2.—*A*, Fascia; *B*, rectus muscle; *c*, peritoneum; *m*, stomach; *G*, outer skin; *R*, edge of ribs; *N*, umbilicus.

The next day, peptonized milk being given with half anounce of brandy in each food allowance, pulse, 80; temperature, 98⅗° F.; to continue rectal injections three times a day. On the 21st, one pint of milk and one ounce of brandy were given three times a day. This was augmented on the 22d by three eggs per diem, and so on, so that after a few days, omitting the rectal injections, he was fed by the artificial opening with two ounces of chopped meat, one pint of milk, one ounce of brandy, and two eggs, three times a day, with a smaller allowance during the night. Later it was found that less finely divided substances could be forced through the same sized tube by the use of a large syringe. though principally food was administered by aid of a small funnel. But very slight irritation from the gastric juice occurred, and this was readily checked by zinc ointment. Little or no leakage occurred, the tube being continuously kept in. At the end of the first week or ten days, when the just mentioned slight irritation occurred, I tried the use of one of

[1] Girard (Correspondenzblatt f. Schweitz. Aertze, November 11, 1888) has suggested that some of the muscular fibres of the rectus muscle should be crossed, so that the extruded portion of the stomach-wall should, so to speak, be more completely surrounded by this new-made sphincter muscle. The present case was satisfactory enough to show that this addition to the technique might be unnecessary.

[2] See Wiener Med. Wochenschrift, November 3, 1886.

Scheimpflug's balloon-catheters (Fig. 2).[1] They answered their purpose well, but they were not durable enough, the rubber softening and yielding under the action of the stomach, and on returning to the use of rubber tubing it was found that the muscular action of the rectus abdominalis was amply sufficient to preserve control of the stomach contents, though the tube required changing every ten days or two weeks, being likewise softened and swollen by immersion in the stomach.[2] At the end of two weeks the patient was out of bed. At the end of four weeks he was moving freely about his room, and had gained from his lowest point, estimated at ninety-four pounds, when stomach was opened, up to one hundred and twelve pounds.

At about the fourth week the treatment of the stricture was essayed. This length of time was purposely allowed to elapse in order to secure improvement ample enough to withstand any of the evil effects resulting from the attempts that might be made to dilate or enlarge the stricture. It was also considered that, should time confirm the impression of the stenosis being a malignant one, the inutility of any decided procedure would be established by the delay. On the first trial, with a fine whalebone bougie, I passed fortunately into the stomach. This ease of entrance was in marked contrast to the difficulty and failure encountered prior to the operation; and as in the urethra when the perineum is opened behind a stricture the rest afforded to the latter allays mucous swelling and muscular spasm, so here in the œsophagus the same amelioration took place, probably from similar causes. A slightly larger whalebone bougie with an olive point, perforated near its point and threaded with a long, doubled, thin, strong silk was passed down and, with a little manipulation, through the stricture into the stomach. It was intended to push this into the latter as far as possible, and then partially withdrawing it, to leave in the way a loop of silk there that might either be washed out through the gastric opening or might be caught by an instrument like the familiar crochet-needle. But the patient objected strongly to further action at this sitting, and the attempt was postponed till the next day, when on trying the smallest conical œsophageal bougie, size No. 7 French at the point and No. 10 in the shank, it was found that it passed with but moderate but decided biting. It was therefore determined to try how far simple intermittent dilatation could be carried before resorting to other and somewhat novel expedients. I had proposed to myself, for instance, had the resistance of the stricture been great or the difficulties of its passage severe, to have utilized my silk thread, when once it had been carried through from the mouth out of the abdominal opening, as a means of carrying a stronger and larger cord, and then drawing through the gastric opening upward either Lange's modification of Maisonneuve's knife, or some other one of the several œsophagotomes that experience has shown to be available, from above downward. Lange's little knife has been used by him with success,[3] and is in fact a quadrangular knife with two of its four corners blunted, and the other two perforated for the attachment of the to-and-fro guiding cords. The smallest sized knife makes only a very limited incision, and thus its employment seems to be safe. Had it become necessary, retrograde dilatation. —*i.e.*, from the stomach upward—would have been tried, by a slightly curved tube leading to the cardiac end of the stomach from the fistula as a guide, and through this the necessary bougies would have been passed.

The rest of the history of the case is extremely simple. Dilatation was practised two or three times a week without any special hitching in the treatment, and in the course of two months was carried up to the largest size olive ended conical bougie that is made, viz., 40 French. When this was reached, finely divided food was allowed to be taken with the milk swallowed, the fistulous feeding being correspondingly diminished. For the last month dilatation has been continued by aid of the long, hard rubber bulbs on whalebone stems, that I have learned to attribute to Dr. Roe, of Rochester, who has done so much in advancing œsophageal surgery. These are some two inches long with the greatest diameter central, and pass through a stricture much easier than the ordinary sized and shaped *bougie à boule*. Beyond No. 42 French it became painful to the patient to use, as the diameter of the œsophagus at the cricoid level was reached for normal dilatation. This is given by Tillaux and Mouton,[1] at this point as 14 mm. in average normal diameter, and that of the cardiac orifice at nearly the same size, with the possibility of dilating the latter orifice, particularly, safely up to a diameter of 17 mm.[2] I had myself found, in two previous instances of spasm at the latter point treated by dilating bulbs, that I could carry dilatation up to a sized bulb which measured 60 mm. in circumference, or a little less than 19 mm. in diameter. Hence I was anxious to augment to a further degree the stretching in the present case, and so resorted to bulbs oval in shape,[3] which preserved an antero-posterior diameter of 14 mm., but whose transverse diameter was gradually increased. In this way the stricture was enlarged up to the size of a bulb which measured 57 mm. in circumference. Since reaching this point, within the last ten days, the patient swallows ordinary food, only taking care to chew it, particularly meat, thoroughly. His weight is now one hundred and thirty pounds, he walks a mile a day, and his spirits correspond to his improved general condition.

As to his gastric fistula, I preferred to show him to the Society at the time that the advantages of the Hacker method might be demonstrated. Hereafter no tube will be kept in the fistula, and it will probably close itself or narrow to such a slight sinus that a light cauterization with nitric acid or with the Paquelin cautery will efface it. Or, at the most, if these fail to destroy the mucous membrane at the orifice, a slight dissection and removal of the same under cocaine will effect its obliteration.

NOTE.—June 15th. The fistula is now nearly closed by nature's contraction. The patient's condition steadily improves, he now weighing nearly one hundred and forty pounds.

[1] Made after design furnished to Mr. Hohlmann, of Tiemann & Co., and subsequently from balloon plugs kindly sent me by Dr. Scheimpflug himself.

[2] I have recently used similar plugs of heavier rubber with good effect in the fecal incontinence following Kraske's extirpation of the rectum.

ON THE DIAGNOSIS OF INTRA-CRANIAL HEMORRHAGE AND ACUTE SOFTENING.

Based on a Study of Seventy four Cases with Autopsies.[4]

By CHARLES L. DANA, A.M., M.D.,
VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

THE present paper is based on a study of seventy-four cases of fatal cerebral apoplexy, embolism, and thrombosis, occurring for the most part in Bellevue Hospital. The list embraces all the cases that could be found on the record books in the last twenty years. These amounted to less than fifty. The remainder occurred in my own service, or in private practice.

There is a slight and manifest source of error in basing clinical facts on fatal cases alone; but with our present knowledge it is the only safe way. I am not aware that any systematic attempt to analyze a considerable number of such cases as these has been made by American observers. Hence I feel that I am justified in publishing the present records, even if the results drawn are not remarkable. I hope at least to call attention to certain lines of observation which will be found helpful in elucidating

[1] Du calibre de l'œsophage. Paris, 1874.
[2] Tillaux: Anatomie topographique, page 470.
[3] Suggested in 1875 by Chassagny (Tillaux).
[4] Read at a meeting of the Practitioners' Society, May 1, 1891.

that most perplexing problem, the distinction between cerebral hemorrhage and acute softening from embolism or thrombosis.

Analysis of Cases.—Of the 74 cases there were of

Intra-cranial hemorrhage		50
Acute softening:		
Embolism	12	
Thrombosis	12	24
Total		74

Intra-cranial Hemorrhages.—Of these there were of

Meningeal:		
Pachymeningeal	7	
Pial and cortical	7	14
Central:		
Ventricular	23	
Corpus striatum and vicinity	7	
Optic thalamus	1	
Corpora quadrigemina	1	32
Pons		1
Cerebellum		3
Total		50

Hemorrhages from the vessels of the dura mater are called *dural* hemorrhages, they may be supra dural, or sub-dural; in the latter case being called hæmatomata of the dura.

Hemorrhages from the pia mater into the cortex, or subarachnoid sac, are called pial or cortical.

Hemorrhages from the central arteries given off at the base of the brain are called central. Hence we have dural hemorrhages, pial and cortical hemorrhages, central hemorrhages, pons and medulla hemorrhages, cerebellar hemorrhages.

Acute Softenings—Embolism.—The arteries involved were the

Right middle cerebral	4
Left middle cerebral	4
Right anterior cerebral	1
Right posterior cerebral	1
Right anterior and middle cerebral	1
Right posterior and middle cerebral	1
Total	12

Right side, 8; left side, 4.

Thrombosis.—The arteries affected were the

Right middle	3
Right anterior	2
Left middle	3
Left posterior	2
Basilar	1
Both middle cerebrals	1
Total	12

Right side, 5; left side, 5; both sides, 2.

Duration of Life in Fatal Cases of Hemorrhage and Softening—Statistics.—Average duration of life in ventricular hemorrhages, 1 to 3 days; in other central hemorrhages, 1 week; in surface hemorrhages, 1 week; in acute softening, 1 to 10 weeks.

Mortality.—When a hemorrhage breaks into the ventricles death occurs in from one to three days. In small primary ventricular hemorrhages life may be prolonged three weeks. The average duration of life in a fatal central hemorrhage is under a week, hence, if a patient passes the first week, he is likely to live longer. It is also inferred that if a hemorrhage breaks into a ventricle, it does so within the first twelve, or, at most, the first forty-eight, hours after the vessel breaks.

In central hemorrhages the usual mode of death is by rupture into the ventricles. Out of 32 central hemorrhages, 26 were ventricular.[1] In surface dural hemorrhages life is prolonged somewhat, the average duration being four to five days, and the limits one to eight. In fatal acute softenings death may come in a few days, but is usually postponed, sometimes for several weeks. The extreme limit is 2.5 months.

[1] Charcot and Bouchard met with only 18 ventricular hemorrhages out of 78 cases. Archives de Phys., vol. i.

Age.—Age is a factor in diagnosis. Hemorrhage is said to occur oftenest between the ages of sixty one and seventy, and to steadily increase after the age of forty and up to the age of seventy. Thrombosis from syphilitic disease is said to be most frequent between thirty and forty, and rarely occurs from this disease after fifty (Gowers). Thrombosis from other causes occurs much later in life, as my table shows.

Embolic softening is admitted to occur oftenest in early adult life. In my cases the ages were as follows:

For Central Hemorrhages, Including Mid- and Hind-Brain.

Age.	Cases
10 to 20	1
21 to 30	6
31 to 40	10
41 to 50	9
51 to 60	6
61 to 70	8
71 to 80	5
Total	45

For Meningeal Hemorrhages.

Age.	Cases.
20 to 30	3
31 to 40	0
41 to 50	2
51 to 60	0
61 to 70	1
Total	6

For embolism and thrombosis the cases are not sufficient to draw very definite conclusions, but the figures are:

Age.	Embolism. Cases.	Thrombosis. Cases.
1 to 10	1	0
21 to 30	2	0
31 to 40	2	1
41 to 50	5	2
51 to 60	1	6
61 to 70	1	2
Total	12	11

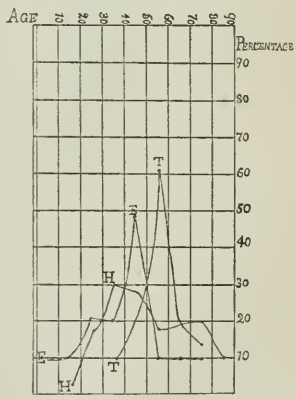

Fig. 1.—Chart Showing the Relative Frequency of Embolism, Thrombosis, and Hemorrhage at Different Ages.

These figures apparently show that hemorrhage occurs with greater frequency before the age of forty than is generally believed. The greatest number occur between thirty and fifty. Embolic softening occurs a little later, and thrombolic softening still later than hemorrhage.

Fagge's table[1] of the ages of 113 cases of fatal cerebral hemorrhage shows a greater preponderance of cases later in life. It may be, therefore, that *apoplexy occurs earlier in Americans than Europeans.*

[1] Science of Medicine.

Side Affected.—Hemorrhages: Lesion in right half of brain, 23 cases; in left half of brain, 23 cases. Surface hemorrhages: Right brain, 4 cases; left brain, 8 cases. Embolisms: Right brain, 7 cases; left brain, 5 cases. Thromboses: Right brain, 3 cases; left brain, 7 cases; both, 2 cases.

In hemorrhage each side of the brain is about equally affected, but in embolism it is usually taught that the left middle cerebral is oftener affected than the right. This difference is admitted by Gowers to be slight (six to five), and according to my figures it does not exist. More emboli affected the right side than the left, in the ratio of seven to four, therefore the side of the lesion and aphasia are points of no diagnostic value.

Arteries Affected and Seat of Lesion.—The middle cerebrals, or some of their branches, are oftenest affected; in hemorrhage, eighty per cent. in my cases; seventy per cent. according to Wernicke. The same is true for embolism, though to a somewhat less extent (seventy-five per cent.). In thrombosis these arteries are also oftenest affected, but here the proportion is still lower (sixty per cent.), and the posterior cerebrals, or the vertebrals or their branches, are oftener involved. Hence, other things being equal, evidence of involvement of the other arteries than the middle cerebral, embolism being excluded, makes the chances more in favor of thrombosis. This applies particularly to the pons and medulla. The middle cerebral is the artery of hemorrhage. The vertebral and its branches, and the posterior cerebral, are the arteries of softening.

Miscellaneous Symptoms.—*Delirium* occurs both in hemorrhage and softening, if life is prolonged more than four or five days.

Consciousness is affected less profoundly and for a shorter time in softening.

Brief Severe Attacks of Loss of Consciousness with some hemiplegia indicate obstruction. Preliminary mild seizures also indicate obstruction. Consciousness is less permanently and severely affected in cortical and meningeal hemorrhages than in central, unless the former are very extensive. It is most severely affected in ventricular hemorrhages. If in a stroke a patient passes rather rapidly from partial or complete consciousness into unconsciousness, it means a ventricular hemorrhage. If he passes into convulsions it means that the clot has broken through the cortex to the surface of the brain. If the stroke comes without loss of consciousness at first, but this supervenes later, immediately afterward, it is more likely embolic.

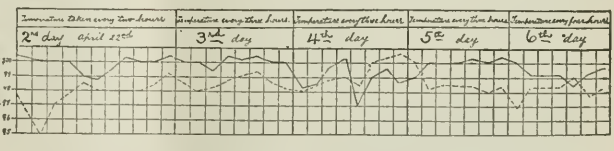

Fig. 2.—Chart Showing Early Subnormal Temperature on the Sound Side in a Case of Acute Softening.

Convulsions.—These were never present as initial symptoms in any case. Convulsions almost invariably indicate a hemorrhage, and that this hemorrhage is dural or pial, or that a central hemorrhage has broken through the cortex. Dural or pial hemorrhage may cause no convulsion, however (3 cases). In one case only did a ventricular hemorrhage cause convulsions. Acute softening, if cortical, may cause convulsions; if central, never. Vomiting never occurred in any case.

Rigidity.—Early rigidity occurs in about half the cases of ventricular hemorrhage, and is more marked on the paralyzed side. It may occur in other hemorrhages, and with quite as much frequency in surface hemorrhages as in ventricular. It occurs, however, much oftener in ventricular than in other forms of central hemorrhages. It occurs but rarely in thrombosis (3 cases), and still more rarely in embolism (1 case).

Pupils.—In hemorrhage the most common condition is contraction and irregularity, with imperfect response to light. As death approaches contraction gives place to dilatation. The contraction is not due to any uræmic complication, as it occurs with equal frequency in patients with healthy kidneys, and dilatation may occur in persons with very much diseased kidneys. Disturbance of the pupils is less marked in lesions of the frontal lobes. Irregularity of pupils is more frequent in lesions of the cortex and meninges, least frequent in ventricular hemorrhages. The dilatation is oftenest on the side of the lesion, owing probably to pressure on the third nerve.

In acute softening contraction almost always occurs, dilatation very rarely, except perhaps just before death. Irregularities are less frequent than in hemorrhage.

Alternate Conjugate Deviation.—When the patient has convulsive seizures during which the eyes turn first to one side (usually that of the lesion) and then to the other side, it indicates a surface or cortex lesion. Otherwise conjugate deviation has no particular diagnostic value.

Sensation.—Some loss of cutaneous sensation occurred in a fifth of the cases of hemorrhage, and in a very much larger percentage of cases of softening. If with moderate hemiplegia there is anæsthesia of the affected side, the probabilities are much more in favor of acute softening. For blocking up the middle cerebrals does not cause anæsthesia, while blocking of the posterior, or even anterior, cerebrals does often do this. I consider the presence of anæsthesia in connection with other symptoms an important point in diagnosis.

The Temperature.—The temperature in cerebral hemorrhage, according to Bourneville, usually falls several degrees below normal during the first few hours after the attack. It then gradually rises to normal or slightly above. In the first three or four days this rise may amount to 101° or 102° F. If the injured brain begins to heal the fever rapidly disappears, and the temperature falls to normal. If, however, the injured brain-tissue tends to further soften and to inflame, the temperature rises steadily and death occurs.

The temperature is slightly higher (by ½° to 2° F.) on the paralyzed side; or it may be normal on the paralyzed side and subnormal on the sound side.

Contrary to Bourneville's experience, the temperature was not recorded as subnormal in a single one of my cases. Still, in most of them the cases were at least a day old before observations were begun.

In acute softening from thrombosis or embolism, the initial fall of temperature is rare, and in the rectum is short in duration. It often affects only the sound side, and on this side may continue low for two days.

In the majority of cases of acute softening the general bodily temperature at first is not affected. Later it may be either equal on the two sides, or slightly higher on the paralyzed side. Just before death it may drop very low (94° F.).

The peculiarities of the temperature in acute softening, as distinguished from those in hemorrhage, are the rarity of primary subnormal temperature and its presence, if it does exist, only on the non-paralyzed side, also the slighter tendency to inequality of the temperature on the two sides, and its slower rise if a rise occurs.

It has been suggested by Bastian that the real temperature disturbance is that on the non paralyzed side, *i.e.*, on the side of the lesion, and that the temperature nerves do not cross. The profound unilateral temperature depression in some cases gives some color to this view; but, on the other hand, experimental physiology very decidedly negatives it.

Temperature disturbances occur most markedly in lesions of the caudate nucleus, to a less extent in menin-

geal hemorrhages, and still less in lenticular or thalamic lesions. Lesions in the crus and pons disturb it most of all.

Urine and Kidneys.—The urine, contrary to the usual statements, was generally of high specific gravity (1.020–1.026–1.030) in hemorrhage and thrombosis. Renal disease was present in a third of the cases of hemorrhage, rather oftener relatively in thrombosis, and less often relatively in embolism. Albumin may be found in the urine and yet no serious renal disease be present.

Chances.—Take a person between thirty and fifty, exclude heart disease, and the chances of his stroke being apoplexy are 19 to 3, or about six to one.

Summary.—The stigmata of cerebral hemorrhage might be stated as follows: Age, thirty to fifty, sudden onset with coma and paralysis together, not paralysis preceding coma; initial and early rigidity; profound paralysis; very unequal pupils; a peculiar alternating conjugate deviation; convulsions, if present. Disturbances of temperature as described. The negative symptoms, so to speak, are absence of cardiac disease, or of weak heart, or extreme age.

These facts may be presented more systematically in the following table:

Hemorrhage.	Acute Softening.
Age, thirty to fifty.	*Early or later age.*
Hereditary history of arterial disease.	
Sudden onset with coma and paralysis occurring together, the coma deepening.	Premonitory symptoms and more gradual onset or more transitory coma.
Initial and early rigidity.	
Very unequal pupils.	
Stertorous breathing and hard, rather slow pulse.	
Peculiar alternating conjugate deviation, as described above.	
Early rigidity.	
Convulsions.	
Peculiar disturbances of temperature, as described above.	
	Presence of weak heart, or endocarditis.
	Slight hemiplegia with anæsthesia.
	The puerperal state.

Between embolism and thrombosis the diagnosis must be based on lines already laid down in text-books. My records show nothing especially new. I have, however, never seen so much temperature disturbance in embolism as in thrombosis. Furthermore, it should be said that the onset of embolism may be accompanied with sudden profound disturbance of conscious and peculiar convulsive movement, of a co-ordinate kind, not like the epileptiform convulsions of cortical hemorrhage.

50 West Forty-sixth Street.

UTERINE HEMORRHAGE OF OBSCURE ORIGIN.[1]

By H. C. COE, M.D.,

new york.

I have selected this subject, not with the expectation of bringing forward any new facts, but with the hope of encouraging an interchange of ideas which may serve to throw light upon certain phenomena that have never been satisfactorily explained. The great advantage of introducing a discussion on a gynecological topic before an audience like the one before me lies in the fact that all useless explanatory details may be omitted. It may be at once assumed that we are entirely conversant with the elementary principles of our art, and that the ordinary forms of uterine hemorrhage are quite familiar to us. It is unnecessary to enumerate the long list of etiological factors which figure in every text-book. We all know from experience how difficult it often is in actual practice to adjust our diagnoses to the classical symptoms which are supposed to go with them. The exceptions are numerous and puzzling.

I need not rehearse the ordinary routine method of examination which we adopt in order to discover the true cause of bleeding from the uterus. Nor is it necessary to remind you that our early training has impressed upon us the folly of remaining content with mere palliative treatment in the face of constantly recurring hemorrhage. The general practitioner may seek to "cover up his tracks" with the astringent douche, the tampon and internal medication. For the gynecologist to pursue such a passive course would argue either timidity or carelessness; he could not plead ignorance. In short, it is an elementary principle that, given a case of uterine hemorrhage, there must be a cause (usually local), and that until this is discovered and treatment is directed toward it we are not doing our whole duty by the patient.

After all, the immediate cause of uterine hemorrhage lies in the endometrium; the remote it is not so easy to discover. What is the source of the menorrhagia in cases of commencing epithelioma of the cervix—is it due, as is taught even now, to "circulatory disturbances" or to actual rupture of small arteries in consequence of advancing ulceration? This can hardly be proved, since there is often no relation between the extent of the disease and the profuseness of the flow. There are certain fungoid, exuberant forms of growth which break down at the slightest touch and bleed freely, yet menstruation is not excessive, while in other cases where there is simply an indolent diffuse induration menorrhagia is a prominent symptom. I offer this suggestion: Menorrhagia in connection with malignant disease of the cervix (cancer of the body of the uterus belongs under another category) is due quite as much to the accompanying hyperplastic endometritis as to the disease of the cervix. It is most marked in the case of large uteri with extensive endometritis. This I have repeatedly demonstrated to my own satisfaction in specimens removed per vaginam. The condition has been mistaken by some German observers for sarcomatous or quasi-sarcomatous degeneration of the endometrium, and has been presented by them as a strong argument in favor of total extirpation, even when the cancer is limited to the portio vaginalis. The condition is nothing more nor less than so-called fungous endometritis, such as accompanies so frequently fibroid tumors, as I have shown in a former paper. The same hyperplasia is noted as a result of congestive enlargement of the uterus from any cause—displacements, perimetritis, inflammatory affections and tumors of the tubes and ovaries, etc. Long-continued congestion of a hollow viscus lined with mucous membrane leads to hypertrophy of that membrane—this is an ordinary principle in general pathology.

This brings us back to the initial proposition, that under ordinary circumstances uterine hemorrhage means a diseased condition of the endometrium, induced by some cause that produces congestive enlargement of the entire uterus, and by natural inference, in treating the effect without seeking for the cause we must act unscientifically.

In order to support this apparently sweeping statement I invite your attention to the following brief notes of cases selected from a considerable number at my disposal:

Case I.—Patient of the late Dr. Hunter's, aged fifty. History of former peritonitis; menorrhagia, with extreme dysmenorrhœa. General abdominal pains, suggesting presence of intestinal adhesions. Menstruation regular in its occurrence, and no evidence of approaching menopause. Malignant disease of corporeal endometrium suspected on account of profuse flow and rapid emaciation. The curette, used on several occasions, brought away simple fungosities. Laparotomy. Uterus moderately enlarged, ovaries and tubes firmly adherent, but small and

[1] Read at the Sixth Annual Meeting of the Alumni Association of the Woman's Hospital, January 19, 1891.

apparently atrophied. Numerous firm retro-uterine adhesions. The adhesions were separated but nothing was removed. Convalescence normal. Patient much relieved by operation; menstruation irregular, but not excessive, for several months when it again became profuse, and the pains returned and were as severe as ever. Patient eventually reached climacteric, but pains were little if at all relieved.

Supposed source of hemorrhage, endometritis fungosa, due to chronic congestion of uterus dependent upon peri-uterine adhesions. It is doubtful if removal of the adnexa would have caused complete cessation of the flow.

Case II.—Patient of Dr. Kletzsch's, referred to the late Dr. Hunter. Aged thirty-five, full habit. Menorrhagia, severe dysmenorrhœa. Adnexa removed, the ovaries being cystic, the tubes normal. Uterus large but non-adherent. Convalescence normal. No effect whatever on menorrhagia, and little relief of pain. The patient insisted on having supra-vaginal amputation performed, which terminated fatally. Uterus three and a half inches deep, general hypertrophy of the endometrium. Right stump transformed into a mass the size of an English walnut (an old hæmatoma), which was adherent posteriorly, keeping the organ in the position of right retro-lateral flexion. No ovarian stroma found. Probable cause of persistent hemorrhage, hyperplastic endometritis from chronic congestion, due to displacement and the presence of the mass at right cornu.

Case III.—Patient of Dr. Kletzsch's, aged thirty. Adnexa removed on account of dysmenorrhœa and menorrhagia. Uterus large. Persistent flow after operation, so that less than a year after the patient insisted on having her uterus removed. Supra-vaginal amputation, with normal convalescence. At the operation no trace of the ovaries or tubes could be found. In one broad ligament there was a cyst the size of a base-ball. Uterus three to four inches deep, in normal position, and no adhesions whatever. Well-marked endometritis fungosa, with general thickening of the endometrium. Cause of persistent flow, endometritis from congestion and enlargement of the uterus, possibly due to the presence of the cyst, since no other cause could be discovered. Would not a thorough curetting have rendered the hysterectomy unnecessary? It might have done so, even if the actual cause of the bleeding still remained.

Case IV.—Patient now under the care of Dr. Buckmaster. A large, robust woman, aged forty (?), had been thoroughly curetted with the sharp curette several times for obstinate menorrhagia. I examined her under ether, the last time, with Drs. Grandin and Morrill, but the os was not sufficiently dilated to allow the finger to be introduced. We thought that we could detect with the sound a small, sessile intra-uterine fibroid, but were not at all certain. No evidence of any trouble outside of the uterus, which was in normal position. The organ was three and a half to four inches deep. It was again thoroughly curetted, the operation being followed by frequent astringent applications. No result whatever. She then came under Dr. Buckmaster's care, who employed various palliative means (including intra-uterine galvanization) without success. The hemorrhage was so obstinate that he inclined to the belief that the patient had malignant disease of the corpus uteri, and at one time thought of performing total extirpation, against which I strongly advised, believing that while there might be an intra-uterine growth, it was certainly not malignant. Vaginal hysterectomy for simple menorrhagia, I am happy to add, is an operation as yet confined to Germany.

Not accomplishing anything by palliative treatment, Dr. Buckmaster, at the patient's urgent request, removed the adnexa, with happy results, as I understand. He will himself state what he found at the operation, and the subsequent condition of the patient. Personally, I believe that the chronic congestion and the resulting hyperplastic endometritis were due to the presence of a small intra-mural fibroma which escaped our notice, and which, perhaps, could not have been removed if it had been located. I have seen just such profuse hemorrhage due to the presence of a polypus not as large as a marble. I am forced to this conclusion in the absence of other causes, especially perimetric adhesions.

The following are a few of my own cases:

Case V.—Patient aged forty, married nineteen years, but never pregnant. Took cold just before a menstrual period, according to her statement, and had suppression, followed by an attack of pelvic peritonitis, which lasted nearly two months. When I saw her she was extremely weak; the uterus enlarged to the size of the organ at the third month of pregnancy, with a hard, tender mass, as large as an orange, behind it. The late Dr. Hunter saw her twice in consultation, and first thought that the body was a fibroid, later a malignant tumor. The diagnosis was cleared up by the suppuration of the mass, and the discharge per vaginam of a number of bones from a four-months' fœtus, that had probably been encapsulated for months, or perhaps years. Menses reappeared, but at frequent intervals and very profuse, so that the patient became extremely reduced. After resorting to palliative treatment for two months (fearing to light up fresh peritonitis), I gave her an anæsthetic and thoroughly curetted the uterine cavity, removing a quantity of broken-down material and fungosities. She began to improve from that time; the hemorrhages ceased. In a few weeks she was able to walk about, and a year later she was practically well, the uterus being of normal size, with no tender indurations around it. In this case I inferred that the enlargement of the uterus and the menorrhagia were due to the old ectopic sac, the development of which, as the history clearly showed, antedated the attack of peritonitis.

Case VI.—Patient aged twenty-five, professional swimmer. Two laparotomies at intervals of a year—both for pyosalpinx—the last by myself. I removed a pyosalpinx and small ovarian cyst from the right side. Until after the second operation the patient had not menstruated profusely. Since then she has flooded at irregular intervals, losing an excessive amount. Examination showed a uterus three inches in depth (it was of normal size at the time I operated), anteverted, with a tender mass at the right cornu as large as a big pea, which I always supposed was the dilated remnant of the tube, to which a coil of intestine might be adherent, judging by the peculiar character of the pain from which the patient suffered. With this opinion Dr. Polk (the original operator) concurred, and with his approval I decided to open the abdomen a third time in order to try to discover and remove the cause of the trouble. I would state that I had already dilated and thoroughly curetted the uterus, removing a few granulations, without the slightest benefit to the patient; the reason doubtless was that the cause of the uterine congestion remained, and that as a result the diseased mucosa quickly re-formed after being scraped away. She was kept under careful observation in the hospital for several months, receiving regular treatment, including intra-uterine applications, without the slightest benefit. She was seldom free from sharp, griping pains in the lower part of the abdomen, and had several profuse hemorrhages, which were liable to come on at any time without any exciting cause.

I opened her abdomen for the third time ten days ago, and found exactly what I had expected, viz., firm intestinal adhesions to the anterior abdominal wall, intra-pelvic adhesions, and a hard, fibrous nodule in the upper border of the right broad ligament. This was examined microscopically, but contained no ovarian stroma. A similar nodule, the size of an almond, removed from the left cornu, was undoubtedly the remains of the tube that had become hypertrophied. Uterus moderately enlarged, movable, and in its normal position. Patient had a perfectly normal convalescence, and I await the result with great interest. Drainage after the second operation, but

not after the first and third. [Six months later the patient still flows as before, although she has less pain. During the past four months she has been under the care of a well-known electro-therapeutist, who has been using electricity regularly *secundum artem*, apparently with little benefit—in fact the hemorrhages are rather more frequent and profuse than before. I now believe that total extirpation of the offending organ offers the only prospect of a radical cure.]

Case VII.—Patient aged twenty-five. Laparotomy for severe dysmenorrhœa, which had been unrelieved by prolonged palliative treatment. Ovaries generally diseased, tubes fairly normal. No adhesions. Uterus small and anteflexed. Convalescence rapid. Menstruation before operation regular and not excessive. Patient left the hospital too soon, and probably had an attack of peritonitis, as she reported to me at the end of a few weeks with her uterus large and tender and extreme sensitiveness around both stumps. For a year she has had constant pain, with flooding at intervals of from three to six weeks. No abatement of symptoms in spite of constant local and general treatment. Uterus three inches in depth. endometrium soft, sensitive, and bleeds easily.

Diagnosis—endometritis fungosa, due to causes above stated. I am trying to persuade the patient to submit to an examination under ether, after dilating the os with tents, so that thorough curetting and free drainage may be effected.

Case VIII.—Prostitute, aged twenty-three. Double oöphoritis and salpingitis of gonorrhœal origin; extreme dysmenorrhœa and constant pain. Menstruation regular and flow slight. Laparotomy. Convalescence perfectly normal. No period for five months, and was comparatively free from pain. She then began to flow profusely at intervals of from ten days to three weeks, and this has now continued for eight months, during which time her virtue has not been above suspicion. Examination a week ago showed that the uterus was large, sensitive, and anteflexed, with general tenderness and induration behind it. Doubtless the continual congestion of the pelvic organs explains the persistent hemorrhages, which have not, however, a periodical character.

Case IX. — Patient aged twenty-eight. Laparotomy for double gonorrhœal pyosalpinx and oöphoritis. Numerous adhesions. Drainage. Normal convalescence. After a period of almost complete relief the patient again complained of the old pains, and has for almost two years had a profuse flow at irregular intervals, due, I suppose, to the uterine congestion caused by the re-formation of perimetric adhesions. [A second laparotomy was performed a month ago, and the operator (Dr. Polk) informs me that he removed a nodule from one stump which apparently contained ovarian tissue.]

Case X.—Patient aged forty-two (?). Referred to me at the Cancer Hospital as a case of malignant disease of the corpus uteri. Extremely anæmic from menorrhagia; no metrorrhagia. Cardiac trouble. Albuminuria. Examination showed a small subperitoneal fibroid behind the uterus, measuring four inches in depth. I feared to administer an anæsthetic, but introduced tents, explored digitally, and used the sharp curette thoroughly; the latter without ether. Removed a quantity of fungosities, supposed on gross examination to be sarcoma. Subsequent intra-uterine applications. Only temporary benefit. Discharged, but returned in a few months, on account of monthly flooding, in the same condition as before. Laparotomy considered unjustifiable by reason of the wretched condition of the patient, and the presence of cardiac and renal trouble. Dilatation and curetting, with removal of granulations, as before. Temporary relief. Referred to Woman's Hospital for intra-uterine galvanization, which was tried faithfully and was continued after she left the hospital, with some benefit at first, though menorrhagia subsequently recurred. [Her physician informs me that she flows as much as ever, and will not survive many days.]

In this connection it is interesting to note the frequent association of fibroid tumors with cystic degeneration of the ovaries. Now cystic ovaries are often a potent etiological factor in menorrhagia (shown by Tait). May not, then, the adnexa be the cause of uterine congestion in many of these fibroid cases, especially when the tumor is small, quite as much as the neoplasm itself?

The deductions which I would make are briefly as follows:

In all cases of uterine hemorrhage, however obscure, the immediate cause of the hemorrhage lies within the uterus—hypertrophy of the endometrium; the remote cause is any condition of the pelvic organs or tissues which leads to chronic congestion of the uterus. The detection of the extra-uterine cause is often extremely difficult, especially if it is localized in the shape of small perimetric nodules or adhesions. The latter condition is rendered probable by the fact that the patient has previously had both ovaries and tubes extirpated, while her uterus remains retroflexed and adherent. Persistent flow after removal of the adnexa is not necessarily due to remains of ovarian stroma. Such a flow is not a true menstruation, since it is more profuse, is atypical, and usually differs entirely from the patient's former monthly period. The uterus will be found to be large, the endometrium hypertrophied and sensitive, bleeding easily.

The prognosis is doubtful. Unless the true etiological factor can be reached and eliminated we can pronounce no positive opinion as to the duration of the hemorrhage.

Treatment.—If there is no positive contra-indication divulse (or better, dilate with tents) and curette thoroughly, remembering that this is usually only a palliative measure. The intra-uterine tampon of iodoform gauze is a valuable adjuvant to this operation. Pelvic adhesions and indurations should be treated according to the ordinary methods. Electricity will certainly accomplish a great deal (whether the cauterization of the endometrium or the reduction of the congested uterus is aimed at), though laparotomy may eventually become necessary.

OUR OPERATING-ROOMS AND METHODS OF PREPARING PATIENTS.[1]

By LEROY BROWN, M.D.,

HOUSE SURGEON OF THE WOMAN'S HOSPITAL, NEW YORK.

I have been requested by the President of the Alumni Association to give a brief *résumé* of the present methods carried out by us in preparing for operations. Responding to that request I submit the following scheme, which is carried out in every detail.

Our operative cases are naturally divided into two classes: those of minor character and those of major import. The former, operations upon the pelvic floor, are conducted exclusively in the operating-rooms of the separate pavilions.

Those of major character are performed in a room lately built for the purpose. This room is separate from the main buildings, yet intimately connected with the rooms to be occupied by the patients after operation.

The operating-rooms in each pavilion have undergone a gradual transformation, so far as the rooms themselves will permit. They have been each furnished with modern plumbing, having all fixings exposed. Each has a sterilizer, in which instruments, after every operation, are steamed for an hour at 212° F. The operating-tables are of the usual gynecological pattern, without upholstering. They are covered by a movable pad encased in a rubber slip. Each of these pads possesses a duplicate cover. After operations these rubber covers are thoroughly cleansed with ammonia, and finally washed with a watery bichloride solution, 1 to 1,000. During the process of cleansing the duplicate is being used. The operating-room for major cases is one twenty-five feet square.

[1] Read at the Sixth Annual Meeting of the Alumni Association of the Woman's Hospital, January 19, 1891.

It has a large skylight and two side-windows. The floor is of Portland cement. This is treated once a week with a hot solution of paraffine in turpentine, and afterward rubbed to a dull gloss. In this condition it is thoroughly impervious to water. The hot and cold water, with its plumbing, is of the same approved pattern as in the pavilion rooms.

The operating table is of iron, and one of Landeau's pattern, bearing a solid rubber cushion one-third of an inch thick. The sponge tables and dressing-stands are furnished with heavy plate-glass tops. The instrument case has also movable glass shelves. Near the operating-table are placed two large-sized sterilizers of sufficient size to accommodate all instruments, towels, and dressings used in an operation. Each of these operating-rooms is under the direct charge of a well-trained nurse, and the effort of each is to excel the others in the cleanly neatness of their respective rooms.

Sponges are bought by the pound, and as received are gritty to the feel. They are placed in small quantities in a cloth bag and beaten well, from here they are placed in running water and energetically kneaded, during which each is examined for parts of shells and spiculæ. This kneading is continued until the water comes off clean. They are then soaked for twenty four hours in a solution of muriatic acid of sufficient strength to be disagreeably sour to the taste. From here they are again placed under a strong stream of running water and kneaded until the water is clean and the sponges freed of all foreign matter. They are afterward kept in a watery solution of carbolic acid, 1 to 20. Sponges that have been used in an operation are washed free of color in cold water, then placed for forty-eight hours in a covered jar containing an ammonia solution of one part strong ammonia to six parts of water. From this they are transferred to warm running water and handled until the water runs away clear. They are then placed in carbolic acid (1 to 20) for future use. The life of a sponge thus used is some two to three weeks, after which it is discarded. All sponges contaminated in any way by pus or suspicious matter are burned.

Ligatures and Sutures.—In the preparation of our ligatures and sutures extreme care is exercised. The member of the staff having this in charge previously cleanses his hands and arms with soap, water, and brush, and covers his suiting with a clean linen gown.

The silk, linen carrying thread and silver wire are each wound upon glass reels which have been in a bichloride solution. These laden reels are boiled for one hour in water. From this they are placed at once in their respective boxes under absolute alcohol. The catgut is bought unprepared in sizes from 00 to 2, also a larger pedicle, size No. 8. This as it comes is in coils of two metre lengths, and of an amber color with a greasy feel. The small pieces holding the strands of each coil closely together are first cut, allowing the entire roll to open out widely, separating each turn from the other. A dozen coils of each number thus loosened are lightly tied together with a long ligature by which they are lifted in and out of solutions. They are immersed for two to three hours in ether and then for a few minutes in alcohol. The gut is then placed in a watery solution of bichloride, 1 to 1,000, for twelve hours. From this it is transferred to a large covered vessel containing absolute alcohol. During the following week the alcohol is changed twice.

Thus prepared the gut is kept under alcohol as a stock supply, and is wound as desired upon sterile reels. Samples of the gut thus prepared have been sent to Dr. Freeborn, the pathologist of the hospital, for examination. From them he has failed to get any cultures, even from the centre of the No. 8 size. The gut after being wound, for fear of having been rendered impure in the act of winding, is kept under boiling alcohol for one hour before it is transferred to reel-boxes, where it remains under absolute alcohol.

If there should be a cause to suspect the antisepsis of any reels of gut, from the alcohol getting accidentally low or otherwise, this reel is boiled for one hour in absolute alcohol and replaced in the box.

Silk-worm gut is bought in bundles of 100, 13 inches long. The curly ends are cut off and a few bundles at a time are placed under a watery bichloride solution, 1 to 1,000, and thus kept permanently.

Instruments.—Before major operations such instruments and needles as will be needed are selected, placed in a tray and sterilized for one hour at 212° F. From here they are removed just before the operation to the instrument trays and kept under water that has been boiled. During the operation no instrument is allowed to get dry.

After every operation in the hospital, the instruments, needles, and sponge-holders in use are first cleaned with brush and water, then steamed at 212° F. for a half hour. The instruments used in major operations have received an extra heavy plating and are not oxidized by being sterilized. By this we are spared the necessity of using polishing powders, which in an aseptic sense is of the utmost importance. Having thus prepared the sponges, ligatures, and instruments we get ready for the two classes of operations in a somewhat different manner.

For operations upon the pelvic floor rigid antisepsis is followed, both before and during the operation.

For those of major character, thorough antisepsis is practised in preparing the patient and her surroundings. During the operation absolute asepsis is exercised.

For minor cases, if their condition will permit, two days previous a compound cathartic pill is given night and morning up to the night previous to the operation, at which time the lower bowel is cleared out by a stimulating enema. The morning of the operation the lower bowel is still further cleared of any matter that may have crept down, by a warm water injection. The night previous the pubes and vulva are shaved, vaginal douches are abundantly used and one hour before the operation a copious douche of bichloride, 1 to 2,000, is given.

The patient being under ether and in position she is surrounded by towels wet with bichloride, 1 to 2,000, under which are rubber sheets.

Instruments are kept in carbolic acid, 1 to 30, and needles with carrying threads in carbolic acid, 1 to 20.

For major operations the morning before the cement floor is washed with bichloride, 1 to 1,000. The operating-table and sponge-tables are treated in the same manner, and all corners and places where dust can collect are carefully cleansed with wet bichloride cloths.

The patient for three days before is given frequent baths, and as to purgatives is prepared as for other operations.

The night before the operation the entire abdomen, pubes, and vulva are shaved and well washed with soap and water. Over the abdomen there is then fastened a towel bearing a thick emulsion of castile soap. This towel extends from the umbilicus to the pubes; with this the patient sleeps. On the morning following, when the abdomen is again cleansed with water, the superficial layer of the skin is found free of all fatty matter. There is then placed over the original site of the soap dressing a towel wet in bichloride solution, 1 to 1,000.

This is not removed until the time of the operation. Before taking ether, the patient is clothed in a clean suit of flannel underwear. The under-vest is tucked well up around the chest, and covered by a sheet folded upon itself a number of times. The lower extremities are wrapped in blankets. The patient being upon the operating table, is covered above and below the abdomen by rubber sheets, then carefully surrounded by towels that have been sterilized for one hour in moist steam. The instruments lie in water that has been previously boiled.

In all operations, the operator and his assistant, including the nurses, are covered by clean linen gowns.

At major operations, our guests are required to wear long gowns, covering entirely their street suits.

In the after treatment of our vaginal, perineal, and cer-

vix cases at present, we differ somewhat from that of former years. As far as possible they are treated without douching, and none are used during the first week unless indicated, or especially ordered by the surgeon. With the perineal cases, our desire is to keep them thoroughly clean, yet as dry as possible. Toward this end, some form of dressing is used. This is changed after each defecation, and whenever the patient passes her water, or has it drawn. With the changing of the dressing, the perineum is always irrigated with a bichloride solution. The dressing of the abdominal wound is one of a damp surgical antiseptic character, which is not disturbed until the seventh day, unless there is an indication. For abdominal sections, in case there may be required some iodoform gauze for packing a general oozing in the pelvis, a couple of fifteen yard rolls, two to three inches wide, are always on hand. These, just before the operation are sterilized for one hour at 212° F., and kept near at hand in a closed jar ready for use.

In the after-treatment of our cases catheters are necessarily of frequent use. With us, as with all hospitals, these have been a source of considerable trouble and annoyance, both to the patient and to the doctor. All care possible may be exercised, and yet soon the rubber catheter roughens, and at no time can anyone absolutely say they are clean. Of late we have been using throughout the hospital glass catheters of a pattern a little different from the straight ones first introduced by Dr. Kelley, of Baltimore. These are boiled after each use, and kept covered by a watery bichloride solution. With these the vesical and urethral irritation following catheterization has been reduced to a minimum.

NOTES ON THE TREATMENT OF TETANUS WITH A NEW VIEW AS TO ITS PATHOLOGY.

By R. F. LICORISH, M.D.,

BARBADOS, WEST INDIES.

To physicians practising in the warmer climates, tetanus is always a disease of the greatest interest, from the fact that it is a disease not only of a most fatal character, but also the one unsurpassed in frightful sufferings to the patient, if we leave out of consideration the fortunately rare hydrophobia. Its relative frequency, too, in such climates adds much to its interest.

It would be quite out of place here to go into the symptoms and course of ordinary cases of tetanus, for however infrequent it may be in certain countries, it occurs often enough for any physician of experience to gain a practical knowledge of it. I shall therefore content myself with recording those rare cases which I have encountered in a practice of ten years, and advocating the course of treatment which has proved the most successful in my hands, as well as hinting at a pathology based on the above observations. The first symptom of this dread disease, as given by most authors, is a stiffness of the muscles of the neck and jaw. This, however, has not been my experience, which goes to show that prior even to that is a pain or indescribable sensation in the epigastrium. In this I am at one with Dr. W. A. Hammond, who lays some stress on the statement that this epigastric pain is the first recognized symptom. Its occurrence he attributes to spasmodic contraction of the diaphragm; this view of its causation appears most reasonable, and has been held by me for many years.

About seven years ago, however, I encountered a case of tetanus in which the significant pain was situated in the umbilical region instead of the customary epigastric site, and since that time I have met with two similar cases. Such a shifting of the site of that symptom, not being in harmony with its accepted cause, I looked about for some other explanation with the result that I now consider tetanus a disease of the sympathetic nervous system, and the pain hitherto attributed to spasmodic contraction of the diaphragm to be pain in the ganglia of the abdominal sympathetic nerves.

This view, too, seems strengthened by the result of treatment now to be mentioned.

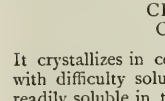
Tetanus, as all are aware, is a disease chiefly met with among the poor and ignorant, and these, possibly not aware of its dangerous nature, and probably, too, from their inability to summon the earliest medical aid, resort to such means as are at their command; such means being, in this as in most other diseases, chiefly purgatives. Now, I have found that as a result of the early resort to purgatives, the disease more readily yields to treatment; and so frequently has this been observed that it is my rule to give a more hopeful prognosis in such cases.

Treatment by purgatives appears to have been that mostly in vogue some forty or fifty years ago, and I have been informed by an aged practitioner that such a course of treatment was more successful than that of the present day. Such a statement, however, is not borne out by Dr. W. A. Hammond's statistics of treatment by purgatives. Let it be borne in mind, however, that the treatment now advocated by me is not by purgatives alone, but in conjunction with that treatment on modern lines—by means of nervous sedatives, etc.—which has proved most successful. This combined treatment, purgatives and belladonna, has proved itself so successful, in the hands of another practitioner of this island, that he has declared to me that since its adoption he has ceased to look on tetanus with his former forebodings. The purgatives giving the best result are the salines. The practitioner referred to above, however, begins with a dose of calomel, and the beneficial result of such a treatment is considered by me to be due to its removing from the intestinal tract all fecal matter, as such under the circumstances must act as direct irritants to the parts chiefly involved. It may also act beneficially by its direct action on the congested vessels of the viscera and contiguous parts. Whether the views above expressed will harmonize or clash with the germ theory of tetanus I am unable to say. I must acknowledge, however, that I see no reason why they should not be in harmony with such a theory. This much, however, must appear plain to all who have had much experience with tetanus: Its germ must be one which may be present with us at any time without giving rise to trouble; one that is harmless until rendered harmful by certain changes brought about through economy by a wound or cold. Recent experiments go to prove that the mischief-maker is not the germ itself, but a product of it, it being affirmed that the introduction of the living germs into the system is of itself productive of no harm.

May 30, 1891.

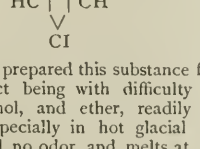
Progress of Medical Science.

Iodantipyrin and Iodantifebrin.—Iodantipyrin is antipyrin in which one hydrogen atom has been substituted by iodine; it is, therefore, iodphenyldimethylpyrazolon, $C_{11}H_{11}INO$, and its chemical constitution is in all probability the following:



It crystallizes in colorless, shining, prismatic needles; is with difficulty soluble in cold water and alcohol, more readily soluble in these menstrua when hot. It is absolutely tasteless, and has no especial odor. A two tenths per cent. solution of this body does not prevent fermentation of grape-sugar. Its melting point is 160° C. Dr. Munzer has studied the effects of this remedy in typhoid fever and in pulmonary tuberculosis, diseases whose temperature curves are well established. As regards the antipyretic effects of this compound, Dr. Munzer's results show that it corresponded absolutely with that of pure

antipyrin, a fact which might be expected; for it is probable that through the action of the hydrochloric acid of the gastric juice this body would be decomposed, and we might, therefore, with reason look for the effects of antipyrin on the one side and iodine or iodide of sodium on the other. Dr. Munzer states that his results have shown him that in all probability such a decomposition actually does take place. He adds that, in doses of from seven and one-half to twenty two grains, marked reduction of temperature is produced, which is accompanied by sweating, but without collapse and without chills. Pulse and respiration are slowed in proportion to the reduction of temperature, while the pulse becomes somewhat fuller and respiration somewhat freer. Eleven different cases are reported in which this substance was used as an antipyretic, the general result confirming the supposition above announced that its action is identical with that of antipyrin. The urine of every patient to whom iodantipyrin was given showed a marked iodine reaction after fifteen to twenty-two grains of this remedy had been given, while the reaction of antipyrin in the urine with nitric acid was but faintly marked. If a perfectly clear, watery solution of iodantipyrin is tested for the iodine test with nitric acid and chloroform, a negative result is obtained, but a positive reaction is produced when either the solution or the nitric acid is heated, or when the reagents are allowed to remain in contact for half an hour. It would, therefore, seem that it is through the action of nitric or hydrochloric acid that the iodine of the iodantipyrin is set free, and the author reports some experiments which seem to show that this decomposition of iodantipyrin actually occurs in the stomach; so that, therefore, the therapeutic action of this remedy is not that of a new compound, but that which might be expected from the simultaneous administration of antipyrin and iodine, either free or in the form of a salt. It thus being seemingly established that this compound possesses no antipyretic effects other than those of antipyrin alone, the question naturally suggests itself as to whether the iodine when so administered in combination differs in its therapeutic effects from iodine administered alone. Here the author's experiments unfortunately are not sufficiently complete to admit of any conclusion. He, however, reports a case of persistent headache, apparently of syphilitic origin, which was rapidly cured by the administration of this compound, while a case of acute articular rheumatism is stated to have been entirely relieved from pain within six hours of the administration of the first dose. Further studies evidently are desirable before any positive conclusion can be formed as to the effects of the iodine in this composition. Iodantifebrin is acetanilide in which a hydrogen atom has been substituted by iodine, the formula, therefore, being $C_6H_4INHC_2H_3O$, and its constitution in all probability the following:



Dr. Ostermayer prepared this substance from paraiodaniline, the product being with difficulty soluble in cold water, in alcohol, and ether, readily soluble in hot alcohol, and especially in hot glacial acetic acid. It has no taste and no odor, and melts at about 181½° C., and in two-tenths of one per cent. solution the substance does not prevent the fermentation of urine or of milk-sugar. The author's experiments as to the action of this substance show that, as an antipyretic, its effects were absolutely negative, and, in fact, no action was noted to follow its administration which could be attributed either to the antifebrin or to the iodine. This, of course, may be explicable as due either to non-absorption from its insolubility, or even, if it is absorbed, that the addition of iodine to its composition has destroyed the activity of the antifebrin. After its administration neither iodine nor antifebrin could be recognized in the urine, an observation which seems to show that this substance is not absorbed in the slightest degree by the alimentary canal; for tests of the iodantifebrin solution give both the iodine test and the characteristic antifebrin reactions. The author's experiments, therefore, are simply valuable as having removed two more substances from the list of new remedies from which wonders may be expected.—*The Therapeutic Gazette.*

Aspergillary Phthisis.—Dr. Potain records the following case of this disease which occurred in a man who came under his care. Six years ago he had pleurisy of the left side; five years ago a second attack, now on the right side. It had to be tapped. He has had cough for the past two years, and three attacks of hæmoptysis. He is wasted. Now he presents signs of early phthisis at the left apex. His expectoration is thick and nummular, but no tubercle bacilli are to be found in it. The patient has the appearance of an individual affected with tubercular phthisis. Bacilli are absent from the sputum under two conditions: 1. Before softening has taken place. 2. When the secretion from the bronchial tubes is so abundant as, so to speak, to drown the tuberculous particles. Instead of tubercle bacilli, the fungus aspergillus was found in the sputum. This fungus has only been found in those who are engaged in artificially overfeeding pigeons. Millet grains soaked in water are taken into the mouth and then blown into the pigeon's mouth. The aspergillus is very common upon millet grains. It establishes itself in certain tissues. Pigeons are affected with a swelling in the floor of the mouth, which is called a chancre. In the centre is found the aspergillus. In the viscera of the pigeon it presents granulations indistinguishable from tubercular granulations. There may even be a giant cell in the centre. The results caused by this mould in the pigeons may be very serious. If the powder be breathed by a pigeon it will die in two or three days of a severe pneumonia. In man the fungus gives rise to an otitis. It has been found in cases of gangrenous pneumonia and bronchial dilatation. Here it finds a suitable medium; but under other circumstances it produces a disease indistinguishable from pulmonary phthisis. Inoculation from cultivations into the veins of animals is very fatal, and the liver is then especially involved. In man the spores are probably inhaled, for the millet grains come from sacks where there is much powder. There are other forms of pseudo-tuberculosis—such, for instance, as that occurring in the gallinaceæ, but this has not been observed in man. The aspergillus may thus give rise in man to a disease which progresses very slowly, and as yet no pathological anatomy is known. The malady is more favorable than tuberculosis. One case—that of a woman where the aspergillus and elastic tissue was found in the sputum, recovered. The affection seems to run its course without fever. The patient must give up his occupation, but as yet there are no other special indications for treatment.—*L'Union Médicale.*

The Evils of Public Hypnotizations.—Dr. Surbled reports the following case in the *Journal des Science Médicales de Lille* for May, 1891. On the occasion of a public exhibition of hypnotism, an intelligent man, aged fifty-two, of healthy antecedents, was profoundly impressed with what he had seen, and continued to talk of the wonders of "animal magnetism" for days after the performance. Soon, however, he began to act rather queerly and in about two weeks became acutely maniacal and died shortly after of encaphalitis. During his delirium all his thoughts were of hypnotism and he was continually making passes as if he had subjects before him. Dr. Surbled regarded his death as the direct result of the impression made upon an excitable brain by the public hypnotic performance.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos 56 and 58 Lafayette Place.

New York, July 25, 1891.

THE NEED OF SURGEONS ON STEAMERS TO SOUTHERN PORTS.

In his Annual Report to the Commissioners of Quarantine of the State of New York, for 1891, Dr. William M. Smith calls attention to the great benefit that would result to this port were it made obligatory upon all companies running steamships between this city and tropical countries to employ ship-surgeons. At present the law provides that "every steamship or other vessel carrying or bringing immigrant passengers, or passengers other than cabin passengers, exceeding fifty in number, shall carry a duly qualified and competent surgeon, or medical practitioner." This is a curious provision, and we fail to see why one or two hundred cabin passengers are not just as much entitled to have their health looked after as are fifty-one steerage passengers. The law presumes that the cabin passengers can provide protection for themselves, but evidently they cannot do so any more than the immigrant passengers, unless each one engages the services of a travelling medical companion for the trip —a rather expensive luxury. Of all the lines whose steamers run between New York and ports in Mexico, Central and South America, and the West Indies, but two employ surgeons. The English do better than this in theory, for even the cargo-boats running between Southampton and the West India Islands have each a surgeon aboard. We may remark, however, parenthetically, that if these surgeons are no better than some they send on ships to this country, it would perhaps be better for the crew were they left to the care of the captain in case of illness.

It is, however, not only for the protection of the passengers that the employment of ship-surgeons is to be desired, but as much, if not more, for the protection of this city from visitations of contagious diseases of the tropics. In consequence of this absence of "duly qualified surgeons, or medical practitioners," says Dr. Smith, "such an intelligent history of cases of sickness among passengers or crew as will afford a satisfactory conclusion as to the character of the disease cannot be obtained. Frequently deaths occur among passengers or crew at the port of departure, or during the voyage, and the health officer is compelled to make up his conclusions as to the nature of the disease from the story of the captain, who knows much more of navigation than he does of disease or its treatment, or from the purser, whose attention to his freight bills has left little time, and perhaps less inclination, to observe the symptoms and to administer to the wants of the sick. The want of intelligent supervision and history of the sick on vessels from tropical ports, particularly of those from yellow-fever infected ports, may leave the health officer in doubt or liable to be mistaken as to the source and character of the disease; in the event of his mistaking the nature of the disease that has occurred, an infected steamer might be allowed to proceed to her dock in the city, and thus the greatest source of danger to the public health be incurred—the source from which numerous epidemics of yellow fever in New York City have originated. The safety and comfort of passengers on steamers running to those ports also require the employment of a competent medical officer."

There can be no question, we think, as to the advisability of insisting upon the employment of surgeons on the steamers running to Southern ports—by that we mean tropical ports—but in order to have efficient men they should be really competent men, and should be so secure in their tenure of office that they could speak the truth, if occasion required, without the certainty of losing their places for so doing. It is satisfactory to note, however, that, despite the absence of medical officers on these steamships, there have been but eight cases of yellow fever admitted to the Quarantine Hospital during the past three years, four of which were from United States war vessels from Port au Prince, while during the three years previous to those, fifty seven cases of the disease were admitted. This difference is doubtless to be attributed, the Report states, to the greater care exercised by masters of vessels to prevent their passengers and crews from going ashore at infected ports, and in anchoring their vessels and receiving cargo by lighters at a considerable distance from infected wharves.

It is to the interest of the owners of the vessels, as well as it is to that of the public, to have competent surgeons on their steamers, for by so doing they are sure to prevent the trouble and expense consequent upon a detention at Quarantine during the time necessary to enable the Quarantine officers to assure themselves as to the character of some suspected case of disease. But, we repeat, these surgeons must be thoroughly competent and must be independent in a measure of the steamship company employing them, otherwise their presence will be only misleading, giving a false sense of security, and perhaps leading the health officer into error instead of helping him to avoid serious mistakes.

Dr. Smith has had much to say in his Annual Reports concerning the inadequacies and defects of the ocean steamship medical service, and no one knows better than he does, the value of a competent service and the worse than uselessness of an incompetent one. There seems to have been little accomplished as yet by these appeals for reform, but that is no cause for discouragement. All reforms require time for their accomplishment, and we doubt not this too will come if its advocates be only persistent and untiring in their appeals to those whose interests are so deeply concerned in it. If the health officer finally succeeds in stirring up public interest in this most important subject, it will be not the least of the good that he has accomplished during his term of efficient service at Quarantine, and we wish him the success which his earnest advocacy of the right deserves.

POLITICS IN OUR STATE INSANE ASYLUMS.

We trust that our readers will direct their attention to an item printed elsewhere, regarding the conference of the Superintendents of New York Insane Asylums in this city. In particular they should note the fact that these Superintendents refused to concur in a resolution to discharge certain patients who were practically recovered, or who at least could be easily cared for by relatives and not at public expense. The reason given for this refusal was that it would be "disastrous politically." This means, if it means anything, that there are persons who are kept confined in our State lunatic asylums and supported by the public mainly because their friends have a political "pull," and do not wish the expense or trouble of taking care of them. It means, also, that the State Superintendents are subjected to political influences to such an extent that they do not dare to do what seems manifestly just to patients and to the public. We evidently still need civil service reform.

A FANATICAL CONGRESS.

A society of medical gentlemen calling themselves the American Medical Temperance Association met last week at Prohibition Park, Staten Island, and delivered themselves of various opinions regarding alcohol and inebriety. Although some estimable physicians were present, and some interesting papers were read, we cannot help but think that the general effect of the "Congress," as it was called, was distinctly bad. When doctors gather together to discuss scientific topics it is supposed that they do so as scientific men, and that they treat subjects in a scientific, as distinguished from a sentimental, way. This is just what the Prohibition Park gathering did not do, and thereby they lowered the dignity and authority of medical science. When a group of medical enthusiasts gather together, and in the name of the profession utter things manifestly absurd and contrary to fact, experience, and common-sense, the profession as a whole is injured by the performance. Because the use of alcohol causes many evils, no medical man is justified in saying that the smell of it invariably kills; and statements almost as extravagant as this were made at Prohibition Park.

Lest we be considered unjust in this condemnation, we present here, as a sample, the principles advocated by Dr. Charles G. Davis and the promoters of the "National Temperance Hospital." These are: "1. Alcohol is a poison. 2. When taken into the system it is not assimilated, but passes the round of the circulation, and is finally thrown off through the organs of excretion, unchanged. 3. While passing through the body it disturbs the various physiological processes, and in this way lays the foundation for disease. 4. It does not stimulate or strengthen, but it depresses and weakens. 5. As it is not assimilated it cannot be a food. 6. As it disturbs every physiological process it cannot be a medicine. 7. There is no disease afflicting the body that cannot be more successfully treated without than with the use of alcohol."

Now, it will be admitted by all informed and honest physicians that nearly every one of the above principles is absolutely untrue. Alcohol is unquestionably a food, using the term in its broad and rightful sense. A man or an animal can live longer on alcohol and water than on water alone. This has been demonstrated, and is absolutely beyond denial; people who still deny it are either ignorant or untruthful. Again, alcohol unquestionably does stimulate, and there are few physicians who have not seen a dangerous crisis tided over by it. It is a medicine also, and one of so much value that we should regard a physician who practised his art entirely without it as in danger of suits for malpractice.

Some of the gentlemen who took part in the Congress referred to did not take the extreme views above indicated, but it was very evident that the convention had no sympathy with those who were not radical in their views. Hence, it appeared that the meeting was convened rather to promote the views and stimulate the enthusiasm of teetotalists, than to secure a sober and wise discussion of a serious social problem.

We do not desire in the least to belittle the evils which surround and proceed from the use of alcoholic stimulants. They are enormous and appalling. But we believe that the best way to fight such evils is to present the facts exactly as they are, and to work out methods of reform accordingly.

INCOMPETENT BOARDS OF STATE MEDICAL EXAMINERS.

The recent *fiasco* of our State Regents in selecting a State Board of Medical Examiners makes very timely a letter written by Professor H. C. Wood to the *University Medical Magazine* on this subject. Professor Wood has always been in favor of State control over entrance into the medical profession; but he suggests that a sharp watch must be kept over the new State Boards of Examiners, or they will become a nuisance. He adds, in illustration, that if such questions are to be asked as those which the New Jersey State Medical Examining Board formulated in the late examination upon Materia Medica and Therapeutics, "it cannot be long before the profession will demand the repeal of the legislation for which it is now becoming clamorous."

Professor Wood asserts that he not only could not answer the questions himself, but should be ashamed of himself if he could.

"Take question number one," he continues: 'What is dialyzed iron, and how is it prepared?' Dialyzed iron is a worthless preparation of iron, which has never been recognized by the United States Pharmacopœia, and is, I believe, no longer used by physicians who are anyway near abreast of the times. In my lectures I simply mention it as a pharmaceutical curiosity that is worthless. It seems to me a first principle of examinations by Medical Boards should be that attention must be confined to official preparations. If the candidate is to be asked a lot of foolish questions upon every kind of preparation, invented by some perhaps semi-addled pharmaceutical brain, how is he to gain any knowledge? He must be forever running after the chaff that is blown away by his teachers.

"Then again, question third. How many practical doctors can give the specific gravity of chloroform, and what use would it be to them if they could?

"Question fourth: 'Give the formula and mode of making camphorated tincture of opium.' If there were

a candidate for graduation in the University of Pennsylvania who could answer this question, I would certainly examine him most severely to see whether he had not grasped at the shadow and lost the substance of true knowledge. Our men are all taught that the strength of paregoric in opium is two grains to the ounce, that it contains some camphor, and that is all that is necessary to know about its materia medica or pharmacy.

"Question number five: 'Give the formula of the compound cathartic pill.' I doubt whether there can be found a doctor in Philadelphia, in sufficient repute to have a practice of three thousand dollars a year, that could answer this question; to know the effect of this conglomeration of cathartics is what the medical practitioner needs. Again, why should a doctor be required 'to describe infusion, decoction, maceration, and digestion,' and not one word asked about the physiological or remedial action of such remedies as opium."

Professor Wood's criticisms are very interesting, and we hope that they will excite attention and be taken to heart by those whose business it is to conduct the State examinations.

THE LAW AND THE MEDICAL STUDENT.

A FEW years ago a student of the Woman's Medical College of this city was rejected on the final examinations. She went to law about the matter, and in some way was able to prove that in fact her papers reached the average percentage necessary for a degree; and she got her diploma.

Recently a student of Bellevue Hospital Medical College after taking his courses there came up for a degree and was refused an examination. He secured a writ of mandamus compelling the College to examine him and grant him his degree if the examination proved satisfactory. The Court of Appeals has affirmed the decision of the Supreme Court in the matter, and the young man must now be examined. We shall be interested in learning if he passes.

News of the Week.

The Disgrace of a Medical Man.—At a special meeting of the Berlin Medical Society, held July 19th, it was voted to expel one of the members on the charge of long-continued and systematic practice of frauds in connection with the municipal sick fund. The physician had been in the habit of drawing fees for fictitious cases, and had made from this source some 10,000 marks.

Dr. James W. Babcock, Assistant Physician at the McLean Asylum in Somerville, has been appointed Superintendent of the State Asylum at Columbia, S. C.

American Public Health Association.—The Nineteenth Annual Meeting of the American Public Health Association will be held at Kansas City, October 20, 21, 22, and 23, 1891. The Executive Committee have selected the following topics for consideration at said meeting: "Sanitary Construction in House Architecture"—(*a*) Heating, (*b*) Lighting, (*c*) Drainage, (*d*) Ventilation; "Railroad Sanitation;" "Meat Supplies;" "Milk Supplies of Cities;" "Arsenical Papers and Fabrics;" "Isolation Hospitals for Infectious Diseases in Cities;" papers upon any of the subjects upon which special committees have been appointed; papers on miscellaneous sanitary and hygienic subjects. Blank applications for membership in the Association can be obtained from Dr. I. A. Watson, Concord, N. H., or Dr. E. R. Lewis, Kansas City, Mo.

The Superintendents of State Hospitals for Insane of New York and the State Lunacy Commission held a conference in this city last week. Among other matters a lengthy discussion was had on the proposition that the State hospitals for the insane should be permitted to receive private patients from any part of the State without restrictions, except those prescribed by law, at a rate not to exceed $10 per week. The proposition was finally agreed to on a vote by hospitals, all being recorded in the affirmative with the exception of Middletown, which declined to vote. The conference refused to concur in the recommendations of the Commission in Lunacy, that as at all the State hospitals there are certain public patients who, while not in condition to be discharged "recovered," may yet be discharged into the custody of relatives or friends or guardians; therefore, in order to reduce public taxation and to put the burden of support of such patients where, under the statute, it rightfully belongs, from the corps of employees some one discreet and competent man be appointed as agent of the State for the specific duty of looking up the relatives or legal representatives of any and all public patients who may be supposed to come within the above-defined category. This suggestion was rejected on the ground that it would be likely to work disastrously politically. It was, however, agreed that there are too many patients idle in the State hospitals who might be employed in the promotion of their own improvement and in the better administration of the hospitals by taking up some industry that may serve the purpose, such as the making of brushes, brooms, mats, rugs, straw braid, baskets, wooden-ware, willow-ware, and other articles, and it was resolved that steps should be taken to that end.

Dr. Albert Skinner, the oldest practising physician in Niagara County, and father of Dr. Winslow Skinner, of New York, died last week at Youngstown, aged eighty-four. He was President of the Niagara County Medical Society for many years, and one of the foremost amateur botanists of Western New York.

Inebriety and Medical Practice.—The Secretary of the State Board of Health of Iowa announces that he is convinced that habitual drunkenness constitutes "palpable evidence of incompetency," as the law reads, and that therefore the physician given up to inebriety should be deprived of his certificate entitling him to practise in that State.

A Case of Leprosy has been discovered in this city in the person of Chin Hop Sing, a Chinese laundryman, who has been pursuing the national avocation here for the last year and a half. A good deal of unnecessary excitement has been caused by the discovery. Leprosy is so slightly contagious that the public danger from it can almost be disregarded. No case is known of the disease originating by contagion in this country.

Curiosities of Science.—It has been found that the serration of the edges of the cranial bones is produced by the continued pulsation to which the vault of the skull is subjected during the completion of the ossifying process. The odor of urine after eating asparagus is due to methyl mercaptan. So says Professor Wencki. Dr. Klingel has found that the height of the cupola of the tympanum averages 4 mm. instead of 5 to 6 mm. A Swiss scientist announces that a gramme of Gruyère cheese contains 90,000 microbes when fresh, and 500,000 when old. This is a genuine count.

There is Another Over-Doctored Country besides America, and it is Belgium, according to Dr. L. Merveille, of Liege, who says that in 1884 the proportion of medical men to population was 42 in 100,000, the corresponding ratio being at the time in France, 39; in Austria, 33; in Germany and Norway, 32; in Spain, 31; in Hungary, 24; in Portugal, 18; in Russia, 16; and in Sweden, 16. The proportion of medical practitioners to area shows the overcrowding of the profession in Belgium in an even more striking manner. There was in that country 1 doctor to every 13 square kilometres, the corresponding figures being for France, 1 to 57; for Germany, 1 to 40; for Austria, 1 to 41; for Hungary, 1 to 87; for Spain, 1 to 96; for Portugal, 1 to 114; for Sweden, 1 to 774; and for Norway, 1 to 538. At the present time there are in Belgium 50 doctors to every 100,000 inhabitants. The rate of increase is shown by the fact that while in 1885 the total number of medical practitioners was 2,250, it had risen to 2,545 in 1889, being an increase of thirteen per cent. in four years.

Dr. John H. Rauch, the active and efficient Secretary of the Illinois State Board of Health, since its organization in 1877, has resigned this position. Dr. Rauch has been a most active worker in the department of sanitary science, and has rendered invaluable service to the cause of medical education and public sanitation. It has been largely through his work that the standard of medical education throughout the country has been elevated to its present position, for the requirements of the Illinois State Board of Health have been largely instrumental in developing a more thorough course of instruction upon the part of medical colleges.

Discovery of the Sex of the Fœtus During Pregnancy.—Dr. R. Ross, of Belfast, writes to the *British Medical Journal:* "For some years I have been able in many cases to forecast the sex of the child before birth from the position in which the mother tells me she feels most distinctly the fœtal movements. Most women can, but some cannot, differentiate the locality. In those who can I find the following rule applies with wonderful accuracy: If the mother describes the fœtal movements as felt chiefly and most distinctly on the left side I confidently predict a male birth; if on the right, I as surely determine the sex to be female." Twelve successful guesses are cited in support of this view.

A New Cure for Typhoid Fever.—Melbourne, Australia, has been having a sensation in the shape of a new cure for typhoid fever (*British Medical Journal*). It is stated that during an operation for hydatids the fetid odor was instantaneously removed by the accidental wounding of the chyle-duct, and so allowing the chyle to reach the cause of the offensive smell. The conclusion arrived at was that the chyle was a powerful disinfectant, and some of the fluid was collected and forwarded for analysis to a gentleman with some knowledge of bacteriology who is engaged as a brewer's scientific expert. Over the brewery this gentleman has his laboratory, and here after some lapse of time the investigations were carried on. It was proved that the chyle submitted contained a yeast and that when placed in contact with typhoid germs, cultivated apart from the human body, it destroyed them. It was also ascertained that the cerevisia could be taken into the human body without any danger. It was then used clinically by its discoverer, who claimed that it not only cured typhoid as no other remedy could, but also severe forms of diphtheria. Its mode of administration consisted in giving the chyle mixed up with food frequently during the day. The curious and entertaining part of this affair now begins. The results, I must explain, were asserted to have been obtained by experiments at the Alfred Hospital. Immediately on the publication of the statements of cure by the surgeon interested, a special meeting of the staff of the hospital was called to discuss the supposed remedy, and after some discussion and examination of charts of the patients so treated, it was resolved as follows: "That this meeting of the honorary medical staff regrets that sensational statements should have been made in the daily papers in association with the name of the Alfred Hospital. That two members of the medical staff have made some trials of this supposed remedy, on the express condition that no premature publication should be made, but the results so far obtained have been negative."

Electrothanasia.—"Electrocution" is a horrible and hybrid word, a veritable etymological monster, and, though now much used, we trust it has not come to stay Electrothanasia, a term suggested by Dr. Peterson, is correct, and the verb "electrothanate" might be constructed from it.

The Late Mr. W. H. Gladstone suffered from a brain tumor, and died from the effects of an exploratory operation.

Suicide of a Physician.—Dr. C. E. Sheppard, of London, who made a special practice of administering anæsthetics, committed suicide recently, on account of a death occurring from chloroform administered by him. No blame was attached to him as he was a careful and skilful man; but he was morbidly conscientious and sensitive and earlier in life had had a mild attack of melancholia.

A Medical Temperance Congress met at Prohibition Park, Staten Island, on July 15th and 16th, Dr. N. S. Davis, of Chicago, presiding. Dr. Davis delivered an opening address in which he treated of intemperance and its causes, and how to put a stop to it. Dr. William H. Porter, of New York, then read a paper on "The Physiological Relation of Alcohol to Food." The speaker said that the common practice of using vegetables to the exclusion of the required quantity of eggs, milk, and meat, was the chief factor in devitalizing the human race and stimulating a strong desire on the part of the system for the more quickly acting alcoholic compounds. The speaker's conclusions were that alcohol could be used with great advantage when the mental and physical powers had been

greatly overtaxed, and in cases of extreme exhaustion, as alcohol called into action the reserved forces of the system. Alcohol should be classed as a medical agent and not as a food stuff. Dr. T. D. Crothers read a paper on "Drunkenness a Disease; its Remedy by Scientific Means." He believed that drunkards should be quarantined and carefully treated until they got over the desire to drink. Dr. E. P. Thwing, of Brooklyn, read a paper on "Climatic Influences as Related to Inebriety," and argued that the climate of this country was altogether of too stimulating a nature, and that drinking was dangerous. Dr. John R. Anderson read a paper entitled "Is Alcohol a Food?" Dr. James Wood in his paper advocated the use of alcohol in certain diseases, but he was attacked by many of the delegates. Among those who took part in the discussion were Dr. J. N. Quimby, of Jersey City, Dr. C. H. Shephard, of Brooklyn, Dr. N. R. Bradner, of Philadelphia, and Dr. M. L. Holbrook. On the second day Mr. Axel Gustafson read a paper on "How to Deal with the Drunkard; with Reference to the New Massachusetts Laws, and New Hospital for Dipsomaniacs and Inebriates." He said that Massachusetts recognizes the fact that persons who drink to excess do so because they are diseased. The Massachusetts Hospital for Dipsomaniacs and Inebriates is now in process of erection at Foxborough, twenty miles from Boston. It will accommodate two hundred male patients, and will cost $150,000. It will be opened during the first half of the year 1892. The central feature of the new system in Massachusetts is intelligent discrimination based upon accurate information. Mrs. Lucy Hall, M.D., of Brooklyn, in giving an account of observations in the State Reformatory for Women at Sherburne, Mass., gave these statistics: Of 204 cases examined, 132 were admitted for drunkenness. More than one-half had formed habits of intemperance before they were twenty-one years old, and one-third between the ages of fifteen and twenty. The results of inebriety, Mrs. Hall said, are not confined to the individual, but transmissible to the offspring of the inebriate. Upon the theme, "What Means a Physician can take to Effectively help to Stay the Ravages of Intemperance," Dr. John Blackmer, of Springfield, Mass., said that the physician could use his influence best by not prescribing alcoholic stimulants. Many pharmacies, Dr. Blackmer asserted, were only "*éditions de luxe* of the corner gin-mill." He advised the use of text-books on hygiene in the public and private schools. An address by Dr. J. Henry Carver, of this city, on "Is Alcohol a Poison?" created a long discussion. "Indirectly, alcohol, taken in larger quantities than the system can properly appropriate, is unquestionably a poison," Dr. Carver said. "In such a case it will produce effects similar in many respects to other acknowledged toxic conditions. That which the system can properly appropriate must be to a great extent gauged by the physical conditions of the individual." The assertion of Dr. Carver, that under certain conditions alcohol can be taken with impunity, brought several gentlemen to their feet, who believed that as a duty in the matter of reform physicians should practise medicine without alcohol.

The Story of the "Fatal Patient."—The daily papers state that a woman visited the Manhattan Eye and Ear Infirmary for treatment about two years ago, that she was suffering from a nasal catarrh, that she was assigned to Dr. Johnston for treatment, and that Dr. Johnston died suddenly two days later. Six months after, the woman again visited the infirmary for treatment of the same disease and was placed in charge of Dr. Pond, who also died suddenly two days after. These singular incidents excited much comment among the staff of physicians, who would jokingly tell any new member of their body who happened to be assigned to the particular department of which Drs. Johnston and Pond had been in charge that he had better beware of this "fatal patient," that designation having been written for amusement against her name. About a month ago the woman appeared again, complaining greatly of her catarrh, but she remarked that she feared the doctors might have some hesitation in attending her case, as her previous visits had been followed by the deaths of the physicians who had taken charge of her case. Her surmise was wrong, for she was promptly attended to by Dr. Phillips, who was in charge, and who had been made acquainted with the grim joke about the "fatal patient," the woman being fully identified to him as the traditional patient. Dr. Phillips was found dead in his bed next morning, having died several hours previously, apparently from heart-failure. As a matter of fact, Dr. Johnston died March 20, 1888, of pneumonia, after a week's illness. Dr. Pond died suddenly of heart disease, April 3, 1889. Dr. Phillips is, we are happy to believe, still alive, having contributed an article to the MEDICAL RECORD of July 18th.

The Psorosperms, a class of organisms belonging to the protozoa, are said by Mr. Jonathan Hutchinson, Jr., and Mr. Bowlby, to be the cause of Paget's disease of the nipple, a disease which should therefore be treated by strong antiseptics rather than the knife.

Obituary.

JOHN LEDYARD VANDERVOORT, M.D.,

NEW YORK.

DR. JOHN LEDYARD VANDERVOORT, one of the oldest physicians in this city, died on July 18th, aged eighty-three. Old age was the cause of his death. He was the seventh son of the late Peter L. Vandervoort, and he had always lived in this city, having been born in a house on the grounds belonging to Trinity Church. After an academic education at Union Hall, Jamaica, L. I., and some preliminary study with Borland & Forest, of this city, he entered Columbia College, from which he was graduated in 1828. The same year he began the study of medicine in the office of the late Alexander H. Stephens.

In 1832 Dr. Vandervoort was admitted as an interne in the New York Hospital, and after the full period of service there he began the general practice of medicine. In 1837 he was appointed librarian of the New York Hospital Medical Library, and he held this position for more than fifty years. He was a member of the Society for the Relief of the Widows and Orphans of Medical Men, the Academy of Medicine, and the Physicians' Mutual Aid Association. Of the last named he was for many years a trustee.

Dr. Vandervoort retired from active professional duties twelve years ago, owing to continued ill health. He continued his duties as librarian, however, up to a recent date, and few figures were more familiar to the profession of New York.

Reviews and Notices of Books.

Wood's Medical and Surgical Monographs for May. Contents: "Differentiation in Rheumatic Diseases" (so called), by Hugh Lane, L.R.C.P. "Mental Affections of Childhood and Youth," and other papers, by J. Langdon Down, M.D. "Cure of the Morphia Habit," by Oscar Jennings, M.D. "Notes on the Examination of the Sputum, Vomit, Fæces, and Urine," by Sidney Coupland, M.D. Illustrated. Pp. 260. New York: William Wood & Co., Lafayette Place.

The articles in the May "Monographs," if possible, excel the high standard of this popular publication, both in interest and practical value. Dr. Jennings, in his excellent essay on the "Cure of the Morphia Habit," gives to the profession the most advanced thought of the age on the subject. He gradually substitutes for the morphia, heart tonics, as sparteine and nitro-glycerine. The details of his treatment, which is the most successful yet devised, is exceedingly interesting. Dr. Lane's article, based on the study of three thousand so-called rheumatic cases, is timely. His differentiation between rheumatoid arthritis and rheumatic arthritis should lead to better success in treatment. The remaining monographs are of equal interest.

Origin, Purpose, and Destiny of Man; or, Philosophy of the Three Ethers. By William Thornton. Pp. 100. Published by the Author.

This interesting little work is a continuation of the author's "Rationalism in Medicine," which received such a flattering reception when issued in 1885. Among other things the author apparently proves that the germ theory of disease is untenable, instituting instead the transmission theory of disease. His arguments are ingenious, charmingly written, and the book is one of great interest.

Surgical Bacteriology. By N. Senn, M.D., Ph.D., Professor of Surgery in Rush Medical College, and in the Chicago Polyclinic, etc. Second edition, thoroughly revised. Illustrated. Pp. 260. Philadelphia: Lea Brothers & Co.

The second edition of Dr. Senn's work on surgical bacteriology needs little comment. It is the best work in the English language, and compares favorably with any in the German. He writes on the now recognized basis that all wound complications and most of the acute and chronic inflammatory lesions which come under the treatment of the surgeon are caused by micro-organisms. A great deal of Dr. Senn's work is based on original investigation, but that he has carefully considered other men's views is evidenced by the fact that references are made to about three hundred authors. The new edition is a great improvement on the old, which, by the way, was completely exhausted in less than two years. New facts illustrative of the relations of pathogenic micro-organisms to the various surgical lesions, and eight new illustrations have been added.

Œuvres Complètes de J. M. Charcot. Vol. IX. Lecrosnier et Babé, aux Bureaux du Progrès Médical. Pp. 540. Paris, 1890.

This, the ninth volume of a most interesting publication, is devoted largely to the contributions which Charcot has made to such subjects as cerebral hemorrhage and softening, metallotherapy and hypnotism, and electrotherapy. As the accomplished editor, Dr. Bourneville, observes, these papers are not of equal value; still, all are interesting and some must undoubtedly be regarded as permanent acquisitions to medical science. The chapter on metallotherapy, while suggestive, embodies certain conclusions with which many medical men are liable to disagree.

Jahrbücher der Hamburgishen Staats-Krankenanstalten. Edited by Dr. Alfred Kast. Pp. 484. Leipzig: Verlag von F. C. W. Vogel.

This really splendid volume represents the first annual report of the Hamburg State Hospital, and more especially of the Hamburg General Hospital.

When it is borne in mind that forty thousand patients receive treatment in this institution every year, it is self-evident that a report upon material of such magnitude must be endowed with something far greater than a mere ephemeral interest.

In truth, in looking through this ample "Report" we are impressed by the enormous amount of labor which has been expended in its preparation, by the conscientious attention to the statistical side of the subject, and by the truly scientific spirit displayed on all sides. Great praise is due the various members of the staff for their interesting contributions to both the surgical and medical parts of the report.

Finally, numbers of splendid colored plates and wood-cuts interspersed in the text serve to classify the various pathological questions involved.

If succeeding volumes are at all comparable with this one, the "Hamburg Hospital Report" cannot fail to maintain a leading position among this class of useful literature.

Jahresberichte über die Fortschritte der Anatomie und Physiologie. Issued by Dr. L. Hermance and Dr. G. Schwalbe. In two volumes, pp. 512 and 694. Leipzig: Verlag von F. C. W. Vogel. 1890.

Like the seventeen volumes which have preceded it, this report of the anatomical and physiological literature of 1889 is replete with matters of interest to those engaged in the special study of these theoretic branches of medicine.

It is quite impossible in a review of this kind to even enumerate the many interesting points embodied in this standard work; we must, therefore, refer the reader to its instructive pages, which will be found to contain the most recent contributions to anatomy and physiology.

Bibliographie française de l'Art dentaire. By Dr. Th. David, Surgeon-Dentist to the Paris Hospitals, etc. Pp. 307. Paris: Felix Alcan. 1889.

As its name implies, the volume before us is a bibliography of that portion of dental literature which has been published in the French language.

Dr. David has rendered an important service in preparing this work not only to his *confrères* in France but also to dentists in other countries who have occasion to consult the periodic literature of their chosen specialty.

A glance at its pages will also serve to show how really considerable are the French contributions to the art of dentistry.

Household Hygiene. By Mary Taylor Bissell, M.D., etc. New York: Z. D. C. Hodges.

This is an excellent little monograph, embodying many suggestions of value in connection with the sanitary regulation of the house as well as of the individual. Women, and especially mothers, should derive many useful hints from its perusal.

La Grippe and its Treatment. For General Readers. By Cyrus Edson, M.D. New York: D. Appleton & Co.

This is the title of a little pamphlet, which is a revision of an article by the same author published in the *North American Review* for February, 1890. It gives a brief history of the disease as far back as it may be traced, and mentions the various names which it has received. It is an edifying essay of forty-six pages, and noteworthy as containing sensible advice in regard to therapeutic as well as hygienic treatment. Mention is made of the epi-

demic of 1557, where, in a small town near Madrid, "the treatment as first practised was bloodletting and purging," and where "two thousand persons, all of whom were bled, died." The references to antipyrine, which has had such extensive use, deserve attention by those practitioners who are so fond of supplanting the powers of nature, as also the remark that "if nature is not too seriously embarrassed by misdirected efforts, the disease usually has a short course." It may be remarked here that great mischief is done in the treatment of most diseases by those who seem to regard febrile symptoms as the principal objects of attack, not perceiving that all through the history of medicine those who have advanced the knowledge of the art have advocated assisting instead of combating curative symptoms.

Dr. Edson regards the grip as presenting two distinct forms, the febricular and the catarrhal. He pays his respects to the Chicago striped microbe, which, he says, "is unique, and must be regarded as a wonderful bug."

Fever: Its Pathology and Treatment by Antipyretics. By Hobart Amory Hare, M.D., etc. Pp. 166. Philadelphia: F. A. Davis. 1891.

This essay, published in 1890 under the title "The Uses and Values of Antipyretics," received the Boylston (Harvard) prize for that year. It is a study upon the effects of antipyrine, antifebrine, thallin, phenacetin, salicylic acid, and cold bathing. An elaborate series of experimental tables of thermal results accompanies the text, and, as well, a series of sphygmograms showing the effect of the various drugs on arterial pressure. The writer classes antipyrine as the foremost antipyretic at our disposal, with antifebrin second, and phenacetin third. He further adds, "for wide-spread application to be put in the hands of the inexperienced, to be efficacious and yet quite harmless, cold sponging is the antipyretic remedy *par excellence;* but even this must be used carefully and with intelligent ideas of its objects and results." Anyone using the remedies experimented upon (and that includes all physicians) can read this essay with profit. As for the author, it only adds another laurel to his already enviable reputation.

Medical Symbolism. By Thomas S. Sozinskey, M.D. Pp. 171. Philadelphia: F. A. Davis. 1891.

This is a collection of historical studies in the arts of healing and hygiene. Commencing with the meaning of symbols in general, the author has written of Æsculapius, Apollo, Hygeia, medical talismans and amulets, pharmacists, symbols, the pentacle, etc. While not bearing directly upon the daily work of the physician, it contains many facts of interest to him.

Materia Medica and Therapeutics. By John V. Shoemaker, M.D., etc. Vol. II. 8vo, pp. 1004. Philadelphia: F. A. Davis. 1891.

The delay in the appearance of the concluding volume of the author's work has been due to his desire to bring it down to the latest date, and to decide on the individual facts which should be given concerning each remedy. He has introduced brief considerations of many substances not in general or frequent use by the profession. Koch's tuberculin is not overlooked in this list. He adopts the name "tuberculinum," and gives the dose as $\frac{1}{64}$ gr. hypodermatically, "cautiously increased." He quotes from the report of Professor Laplace quite freely, but is very cautious in his own personal statements. He says "up to the present time no well-authenticated case of marked tubercular disease of the lungs or joints has been cured and it (the lymph) is now only thought to be of avail in incipient cases of phthisis which we know are amenable usually to hygienic treatment without hypodermatic injection. Cases of lupus which have been thought cured have subsequently returned with the disease as intractable as ever." The non official list of drugs includes jequirity, all the new antipyretics and hypnotics, heart stimulants, aristol, cheken, and many others, some of which we frankly confess, we never heard of. The value of the book lies in the fact that it contains all that is authentic and trustworthy about the host of new remedies which have deluged us in the last five years. Some of them will be short-lived, others are valuable additions to our means of making sick people more comfortable and increasing their chances of recovery. The pages are remarkably free from useless information. The author has done well in following the alphabetical order.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 1, 1891.

George L. Peabody, M.D., President, in the Chair.

Pyocyanine in Epithelioma of the Cheek.—Dr. R. F. Weir presented a man whom he had treated for epithelioma of the cheek by injections of pyocyanine, with negative results.

Gastrostomy for Impassable Stricture of the Cardiac End of the Œsophagus.—Dr. R. F. Weir presented the patient and related the history of the case (see p. 88.)

Diagnosis of Intra-cranial Hemorrhage and Acute Softening.—Dr. C. L. Dana then read a paper with this title (see p. 91).

Dr. Andrew H. Smith inquired of Dr. Dana whether galvanism applied to the neck, with the view of producing contraction of the vessels, had been tried in cerebral hemorrhage.

Dr. Dana replied that he did not know. He should doubt whether galvanism would have any effect in that direction when applied to the neck, unless the current were very strong, strong enough in fact to cause unconsciousness. He had in his own person passed a current produced by fifty cells through his head, one pole on the forehead, one on the back of the neck, without marked effect.

Dr. Smith thought that if one pole had been applied to the angle of the jaw he would have got a very decided effect.

Rigidity.—Dr. Beverley Robinson asked Dr. Dana whether secondary rigidity of the lower and upper extremity, and after a week or so tendency to mental excitement, would be of aid in differentiating between hemorrhage and embolism.

Dr. Dana thought that late rigidity was not of much value in differential diagnosis. He thought it depended rather upon the amount and location of the lesion than upon its character. There was believed to be more mental disturbance after acute softening.

Dr. Robinson said a specialist had expressed to him in conversation the view that rigidity and mental disturbance spoke rather for embolism as against hemorrhage. He then asked Dr. Dana whether bromide of sodium might not be useful in cerebral hemorrhage by tendency to close the vessels and by its action on the heart.

Dr. Dana replied that he had had no experience with bromide of sodium. He doubted whether it would be of any particular value. He said that Dr. Julius Althaus claimed very striking results from injection of large doses of the fluid extract of ergot, but his experience seemed to stand alone.

Frequency of Cortical Hemorrhages at Bellevue Autopsies.—Dr. Herman M. Biggs said he had been impressed by the frequency with which cerebral hemorrhage, meningeal in particular, was found at autopsies on persons dying in Bellevue cells. Many of them resulted from traumatism, and a good many from pachymeningitis hæmorrhagica. Many of them, apparently, would have been amenable to surgical procedures. That day an au-

topsy was held in a case in which there was found a large cortical hemorrhage on the left side, due apparently to traumatism on the right side, without fracture of the skull and with very slight laceration of the brain. He had seen as many as three such cases in a week from Bellevue Hospital cells. Nearly all the patients had been admitted for alcoholism, and a large proportion treated for that condition until death occurred.

The Policeman's Club.—The President said he had seen a great many cases like those Dr. Biggs had described, with which he believed the policeman's club had had much to do. In many instances the men were, doubtless, alcoholic when arrested, more or less rebellious, were hit by the policeman's club, and being found more or less "sleepy" next morning, were taken to the hospital, there were supposed to be alcoholic, and died. He had repeatedly found extensive cortical hemorrhage without any fracture whatever to show that there had been a blow upon the other side.

Dr. Biggs added, in a large proportion of cases the laceration of the brain was very insignificant.

The President said, very insignificant, but the hemorrhage was very large.

Dr. Francis Delafield thought the cortex was really more changed in these cases than would appear from simply looking at it. There was always some laceration evident, but if one went over the field carefully he would probably find a good deal of disintegration of tissue, at least if the man lived long enough for necrosis to take place, which was the direct result of the blow.

Dr. Biggs asked the last speaker whether he thought, if the pressure were removed by a surgical operation, a large proportion of the cases would recover.

Dr. Delafield expressed his doubts. The hemorrhage was not the whole trouble. The effect of the blow in producing necrosis of the cortex of the brain was quite as important as the hemorrhage or concussion. He thought it was a very curious fact that blows were likely to produce necrosis of tissue without, necessarily, laceration.

The President asked, without laceration of blood-vessels?

Dr. Delafield replied, yes, without hemorrhage. One saw this in the liver, and also in the kidney.

Dr. Weir fully agreed with Dr. Dana that something should be done surgically in traumatic cerebral hemorrhage, and said that success often attended such interference. In other forms of supposed cerebral hemorrhage, however, he felt more doubtful, although there had been a few cases reported in which hemiplegia or aphasia had been relieved. In a case which he operated upon without success, the history being obscure, Dr. Dana suggested that it might be an embolism instead of a hemorrhage, and later the autopsy proved that it was.

Dr. Delafield said, with regard to traumatic hemorrhages, that there was a great deal of difference, he thought, between cases in which the hemorrhage was immediately beneath the seat of the injury and those in which it was on the opposite side of the brain. Cases in which the hemorrhage was immediately beneath the seat of the injury were unquestionably benefited by an operation, but those in which the hemorrhage was on the opposite side were not so likely to be benefited.

Dr. Weir asked whether they would not be benefited if the seat of the lesion was known and could be reached.

Dr. Delafield thought not. He thought that in such cases the thing of consequence was the lesion of the brain. He would lay a good deal more stress than Dr. Dana seemed to do on rigidity. He thought that rigidity of the muscles coming on later was a great deal more common in embolism than in hemorrhage.

The President asked if the rigidity was not due to secondary degeneration, which took place in both cases.

Dr. Delafield replied that theoretically this was true, but that clinically he had noticed rigidity oftener in embolism.

Valvular Disease.—The President thought that the value of valvular heart disease in making the diagnosis of embolism had been overestimated. He thought that embolism was pretty common without valvular disease. Of course the presence of a heart-murmur would tend to confirm the supposition that the case was one of embolism, but its absence would not necessarily favor hemorrhage. He had been rather sceptical with regard to the efficacy of drugs in these cases. He thought that if the arterial tension was great, they should be used as they should be in other cases under like conditions; but to give aconitia, or nitroglycerin, or other drugs simply because of the hemorrhage was, he thought, useless.

Dr. Dana thought the point made by Dr. Peabody was a good one. He had not meant that aconitia should necessarily be given in all cases. Replying to his interrogatory as to the youngest patient in his list, he said it was a case of embolism in a boy of nine, the diagnosis being made by Dr. Janeway.

The President said he had had a very interesting case some time ago, one of very extensive ventricular hemorrhage with rupture through the base of the brain, in a boy aged nineteen years, who had been found comatose at half-past three in the morning. The father was absolute sure that he was well two hours before. The hemorrhage had apparently come on while he was asleep. He died before daylight, and the autopsy revealed very general arterial sclerosis, a congenitally small heart, and left ventricular hypertrophy.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 21, 1891.

Alfred L. Loomis, M.D., President, in the Chair.

Extra Assessment.—On motion of the Secretary, Dr. A. M. Jacobus, the recommendation of the Council to assess resident fellows ten dollars each to meet the deficiency for the current expenses, was unanimously adopted.

Photograph of Dr. Agnew.—The Academy accepted, with thanks to the donors, a steel engraving from a photograph of Dr. C. R. Agnew.

Why Syphilis is not Aborted by Early Destruction or Excision of Its Initial Lesion.—Dr. Robert W. Taylor read this paper (see p. 1).

Some Suggestions for Deep Medication in Posterior Urethral Catarrh.—Dr. E. L. Keyes read the paper (see p. 85).

The first paper was not open for discussion, but Dr. A. Jacobi ventured to ask the author a question. Many authorities claimed that the use of iodide of potassium or mercury should not be resorted to until the secondary symptoms made their appearance. Dr. Taylor had demonstrated the fact this evening that constitutional syphilis existed as soon as, and even before, the initial lesion became manifest. This had always been the speaker's belief, and it demonstrated clearly why in the past his cauterization of the initial lesion for the abortion of syphilis had proven useless. But he thought it also showed that specific treatment should not be postponed until the eruption made its appearance. He asked Dr. Taylor if this was not a legitimate conclusion to be drawn from his paper.

Dr. Taylor replied that the clinical experience of many eminent men, and his own, went to show that in practice patients got along better who did not receive the iodide or mercurial treatment until the secondary eruption had made its appearance. It was very desirable to obtain the moral effect of the eruption appearing at the regular period, in order to secure submission to thorough and necessarily long-continued treatment.

Dr. Jacobi was not convinced. He felt more interest in the patient's future physical welfare based on early

treatment, than hope of influencing morals which were already rather shaky.

More than One Method of Treatment.—Dr. S. Alexander said that at present much attention was being given the subject of gleet, especially among genito-urinary surgeons, and considering the danger of going to extremes in a single method of treatment, he thought we could not have too many valuable papers like the one presented this evening. Touching on some of the points brought out, he expressed the view that gleet could not be considered one of the little things of life, in one sense. Those who had listened to a paper by Dr. Brewer during the winter, and the discussion thereon, would remember the fact which was then demonstrated, that the gonococcus might harbor in the urethra and be awakened to activity even after the discharge had nearly disappeared. One should, therefore, forbid intercourse as long as the gonococcus was present. The methods which the author had described for differentiating between a urethritis in the anterior and posterior urethra, had been practised by him with much satisfaction for a number of years. He had used nitrate of silver and sulphate of copper, and could speak favorably of them, but he was surprised that the author had been able to inject such a large amount of the solution. He thought he had on several occasions caused increased discharge by ten or fifteen minims of even a mild solution. The bladder would not stand a very strong solution of nitrate of silver; four grains to the ounce would cause a good deal of pain.

The Endoscope.—He thought that, as an aid in diagnosis, the endoscope should be used. It gave him a great deal more confidence in the treatment of the disease, and enabled him to judge better of the strength of solution which should be employed. Internal treatment was of considerable importance; the urine should be kept as bland as possible, not by giving an excess of alkalies, but by diluents.

Gleet not a Trifle.—Dr. L. Bolton Bangs expressed his interest in the paper. Gleet could not, in his opinion, be considered one of the little things of life. It was the cause of much mental suffering, if not of moral torment, and to its cure the physician might well devote his time and highest degree of skill. He thought more attention might be given the pathology of the affection, which varied somewhat according to its location. In this direction the endoscope was of considerable value. It rendered the diagnosis more positive, and added safety and rapidity to the treatment. Regarding the application, he had come to rely principally upon solutions of nitrate of silver in varying strength. He did not think that in using this agent it was sufficient to simply inject; it should be placed upon the diseased spot. In some very persistent cases, having determined the location of the urethritis to be in the bulbous urethra, he had injected ten or fifteen minims of a solution of nitrate of silver, one or two grains to the ounce, held it there, kneading the parts so as to drive the solution into the follicles, which seemed to be in those cases the hiding-place of the disease.

In tubercular cases, to which allusion had been made in the paper, he had found instrumentation and solutions of nitrate of silver likely to aggravate the discharge, but a solution of iodoform had proven beneficial. He agreed with what had been said against unnecessary use of instruments. It should be borne in mind that the penis was not made to put instruments into, and should be thus inflicted only when necessary. Still, there were cases of strictures of even large calibre in which it was humanitarian to overcome them.

Nitrate of Silver in Gonorrhœal Cystitis.—Dr. G. E. Brewer had first made use of Dr. Keyes' modification of the Ulzman syringe in injecting the deep urethra, some years ago, at Roosevelt Hospital, and had found its use result in the cure of a number of cases where treatment previously directed to the anterior urethra had failed. He had met with some cases of gonorrhœal cystitis, with bloody urine and painful urination about every five minutes, which he had relieved quickly, and ultimately cured, by injection of a solution of nitrate of silver, five grains to the ounce, into the deep urethra, some passing into the bladder. He had cured cases of granular condition at the neck of the bladder by injections of nitrate of silver, when, but for this mode of treatment, cystotomy would probably have been proposed by some surgeon.

Dr. F. T. Brown thought the methods of diagnosis described by Dr. Keyes would usually do away with the necessity for specular examination, but he had found the latter practical in most cases even of deep urethritis, and a valuable means of making a more positive diagnosis. If only the bulb was to be examined, and parts anterior to it, he thought one should always make an ocular demonstration if no obstruction were in the way. He exhibited a mucoid thread, five or six inches long, which contained some gonococci, found in the urine of a man who had ceased to have any discharge; it had been coiled up in the posterior urethra, and showed the danger of such a patient spreading disease by intercourse. He also exhibited two instruments which he had devised, one for application of medicinal substances in ointments.

Dr. F. R. Sturgis had come to make applications directly to the diseased spot, instead of by general injection. Nitrate of silver stood first, sulphate of zinc was useful, and he had applied it successfully rubbed up in vaseline, and also in cold cream. There were some cases in which the discharge depended upon the constitutional condition, as anæmia, etc., and a sea voyage or change of climate was necessary.

Credit to Ulzman.—Dr. R. W. Taylor appreciated the diagnostic value of the methods mentioned in the paper, and the usefulness of Keyes' syringe, but said that sometimes injury resulted from this, especially in unskilled hands. He had been surprised that nothing had been said about Ulzman, who, he thought, had done more to relieve chronic urethral discharges than anyone else. There was no portion of the human economy which required more gentle treatment than the male urethra, and one should use caution in employing a stiff silver catheter, whether it was in the form of Ulzman's syringe or Keyes' modification. A small catheter with fifteen holes near the end was a valuable instrument in applying nitrate of silver solutions, the solution not to be strong, for he had seen ten drops to the ounce cause much pain. The nitrate of silver solution could be neutralized by following with a saline injection. He employed the classical injection of Ulzman many times a day.

Dr. Keyes closed the discussion. His chief criticism of the discussion was that it had gone beyond the scope of his paper. A large quantity of a strong solution of nitrate of silver should not be used. He rarely employed more than ten grains to the ounce, seldom that much.

ALUMNI ASSOCIATION OF THE WOMAN'S HOSPITAL.

Sixth Annual Meeting, held January 19, 1891.

Uterine Hemorrhage of Obscure Origin.—Dr. H. C. Coe read a paper with this title (see p. 94).

Dr. Wylie said that Dr. Coe referred in his paper to the use of the tampon and sponge-tent. He had supposed, to a young gynecologist at least, these things had become obsolete. He was satisfied that the use of a sponge-tent was a more dangerous practice than the performance of a laparotomy, and the tampon bears a very close relationship to it. He spoke of the tampon in this connection because he had been called in quite a number of cases during the last few weeks where the tampon had been put in when the hemorrhage had been simply due to an acute inflammation of the tubes and ovaries.

Dr. D. Emmet would like to ask why Dr. Coe in his

paper persisted in calling the condition he finds in the uterus by the name of endometritis. He thought it was begging the question to use that term, for endometritis means an inflammation of the endometrium. He gives no symptom of a primary inflammatory process, but in each case shows some obstruction to the pelvic circulation from some mechanical cause, of which this congestion of the uterus and its effect would naturally be a symptom. He thought this use of the word endometritis a very mischievous one to employ, for it gave them an erroneous idea of its pathology and causation. He would like to direct Dr. Coe's attention to the use of this term and hear from him in reply.

Dr. Goffe said that he had had within the past few years a uterine hemorrhage due to a salpingitis. There was one case he could recall to mind he saw in consultation with Dr. Janvrin a number of times. She had an excessive hemorrhage, with the uterus somewhat enlarged, and had excessive menorrhagia and metrorrhagia, so that she had been curetted three times within the last eighteen months. At each curetting a large quantity of fungosity had been obtained which had been on two different occasions examined by two different pathologists, one of whom declared it to be a cancer, the other simply a fungosity. The point he wished to emphasize was this: Hemorrhages occur, fungosities reproduce themselves, and though the uterus has been curetted, still they re-occur.

The constitutional condition of the woman has improved as a result of this treatment and the doctor has not seen fit to resort to a radical operation. He has had a consultation with Dr. Polk, and they both agreed to defer any radical measure. Another case he saw last week in which he assisted at a laparotomy a year ago for tubal trouble. The appendages on both sides had been removed and through a drainage-tube which had been introduced she had an excessive flow of blood from the adhesions that had formed. Her pulse was good, the hemorrhage stopped spontaneously, and the patient made a good recovery. She had been curetted thoroughly for uterine hemorrhage and a very slight amount of fungosity had been obtained. Last week I saw her and was not able to discover any trouble within the uterus. During the past week she has been suffering from constant hemorrhage. Some of the ovarian tissue had been left in on both sides, which he thought to be the cause of it.

Another case came under his observation last Thursday which he had curetted five years ago. He had been unable to find any other cause for the hemorrhage but that of chronic endometritis. Dr. Emmett objected to the use of that term. He did not see why they should not have a chronic endometritis of low grade. The woman had been relieved of her trouble till the last few months, though she had been curetted five years ago. He curetted her again this morning, as the hemorrhage returned.

The walls of the uterus were very hard, being in that state Dr. Wylie calls fibroid degeneration. They were separated from each other and he could pass the sound in with considerable ease, proving that a cavity existed. So that they should look upon these cases as the type of a great variety of cases, for they certainly exist.

Dr. Van Ramdohr would like to ask Dr. Coe if he understood him to say that he performed the laparotomy at the request of the patient. If he understood him to say so, was there ever in his mind an indication when the patient might tell the doctor what to do.

Dr. Currier would like to ask if he understood Dr. Coe as saying in his paper that a very large number of hemorrhages from the uterus were due to hyperplasia of the mucous membrane with congestion. He thought if they studied the cases carefully they would find many in which the cause was obscure. They would find that the cause did exist there, yet he understood him to state in the early part of his paper that a large number of the hemorrhages which occur in cancerous diseases—even in cancerous disease of the vaginal portion of the cervix—were due more to a congestion of the mucous membrane than to a breaking down of the structure of the cervix itself. While such a condition as that may occur occasionally yet he thought the cases were too numerous, and the hemorrhage so obviously from the structure of the cervix itself, that they could conclude from absolute observation that such was the case. The tissues are so much infiltrated that the most careful examination with the speculum results in a breaking down, apparently, he would say, as soon as the instrument had been introduced. The statement that hemorrhage from the uterus was due entirely to a diseased condition of the tubes and ovaries was not absolutely susceptible of proof. They knew too well that there are numerous instances on record where hemorrhages do occur after removal of the tubes and ovaries. He might recall one case that came under his observation where removal of one diseased tube and ovary was followed by a profuse hemorrhage for a time, then came a recurrence, and curetting, which secured the same results as Dr. Coe speaks of in his paper. Removal of the hypertrophic mucous membrane relieved the trouble.

There was a point that had not been referred to which he thought deserved a passing mention in this connection, and that was the existence of the nerve Dr. Johnson described some few years ago as passing from the Fallopian tube and running into the uterus. This nerve, he (Dr. Johnson) maintained, was the factor which controlled hemorrhage in many cases in which the tubes and ovaries had been removed. If that theory be correct, and the nerve retained its function, then removal of the tubes and ovaries will not be followed by profuse hemorrhage, for the diseased condition of the endometrium remained. The cutting off of the nutrition of the uterus by ligation of the nutrient arteries would, he thought, be a more efficacious manner of controlling hemorrhage than by removal of the tubes and ovaries. He could recall one case in which that operation had been done, in which there was a fibroid degeneration of the uterus, and though the disease was not checked, showing evidently that the nutrition of the uterus had not been entirely cut off, yet there was no hemorrhage. The woman had been suffering from excessive hemorrhage before that time and there had been no recurrence since.

Dr. Boldt thought that Dr. Coe was unquestionably right in stating that there were uterine hemorrhages of obscure origin. We do have cases in which we may curette time and again, do a laparotomy and cauterize the endometrium, and still hemorrhages do occur. Dr. Currier had alluded to the fact of Dr. Johnson calling attention to a particular nerve which seems to control uterine hemorrhages, and he (Dr. Boldt) had sometimes looked upon the recurrence of uterine hemorrhages as being due to that cause. Though we might be able to control a large majority of hemorrhages by curetting and intra-uterine treatment, still there would remain a number of cases of hemorrhage which it was impossible to control save by a radical operation. If there was a recurrence of the uterine hemorrhage after the removal of the ovaries, then it seemed to him that the real cause of the hemorrhage was due to the fact that this nerve had not been ligated.

Dr. Wylie had touched upon the question of fibrous degeneration. Now, because Dr. Noeggerath, or any other man, had spoken of fibrous degeneration, that was no good reason why we should speak of it. We had no fibroid degeneration of the endometrium nor of the uterus. There are fibroids of the uterus, and if these fibroids are found in the endometrium we had fibroids and not fibrous degeneration. It has never been proved by anyone that there was a fibrous degeneration of the endometrium or uterus. Hemorrhages due to fibroids are never, as a rule, due to such small fibroids as these, to his knowledge. By the means of thorough curetting and intra-uterine medication we may be able to cure them. There were hemorrhages of perfectly obscure origin, and we did not know how to relieve these except by some radical form of operation.

Dr. McLean wished to say a few words in regard to an impression that appeared to have become current, and which he has had abundant evidence to contradict, and that was, that if a portion of the ovary be permitted to remain after laparotomy, it was believed to be a sufficient explanation for the hemorrhages which occurred. He did not consider that to be sound doctrine. He had performed laparotomies, and had been obliged to leave behind a portion of the ovary and noted the subsequent condition of the patient and there had been no hemorrhage. One patient he operated npon had not had a recurrence of the hemorrhage in seven years, normal or abnormal, since the operation.

Dr Coe, in closing the discussion, said that Dr. Wylie gave him a cold chill in alluding to sponge-tents, since he (Dr. Coe) had always been taught to regard them with aversion, and had never used one. He agreed with Dr. Wylie in his statement that laparotomy should not be done for dysmenorrhœa and hemorrhage alone.

Dr. Wylie had alluded to so-called fibroid degeneration of the Graafian bodies. This had been described under various names, and he had an idea that the new disease described by Dr. Mary Dixon Jones as malignant disease might be only a form of such degeneration. It is not known whether these peculiar corpora fibrosa are pathological or physiological. He agreed with Dr. Emmet that the term fungous endometritis was not a happy one, and he simply used it from analogy. He also objected to the use of the term chronic cellulitis. These are simply results. Hypertrophic rhinitis was the result of a former acute inflammation, so was chronic oöphoritis. It would be better to usè the term fungoid degeneration of the endometrium, or simply hyperplasia, to express this condition. He used the term as suggested by the Germans, although it is not an inflammation but the result of prolonged congestion, and being such, he did not regard it as a primary condition. He would say, in reply to Dr. Van Ramdohr, that he should certainly not perform a laparotomy only at the request of the patient, but in the case of a patient with recognized pelvic disease who had suffered for a long time and had used palliative treatment with no good result, and had insisted upon an operation, he would feel justified in operating. In regard to Dr. Currier's criticism, he would say that he had distinctly excluded those exuberant malignant growths of the cervix in which the hemorrhage was clearly due to the breaking down of the vascular neoplasm, and had purposely confined himself to cases of commencing epithelioma and to those more advanced cases in which the cervix was indurated and non-vascular. One can make out by palpation if the cervix is indurated, and when the sound is passed up to the uterine cavity and the blood comes from the endometrium, you can say in such cases that the source of the hemorrhage is within the uterine cavity. His statement was based upon an examination of twenty cancerous uteri removed per vaginam.

He thought the hemorrhage was increased by this hyperplasia of the endometrium. If they had a cancer of the cervix, plus fungoid degeneration of the endometrium, they had a cause for profuse menorrhagia. He had been very much interested at the time Dr. Johnson made the statement in reference to his trophic nerve, but he did not see how one could tell when he had tied it. He thought this was largely a matter of conjecture, and in fact has not been proven. He was glad to hear Dr. McLean say that ovarian stroma may remain without giving rise to menstruation, as Dr. Myer, of St. Louis, had published a paper in which he makes the statement that hemorrhage after laparotomy was always due to the presence of this ovarian stroma. He did not think that statement to be true. There was something back of it all which has not been satisfactorily explained to his mind. The Germans had written on this subject, and one writer had shown conclusively that these hemorrhages may be due to perimetritic nodules. He had demonstrated it in those cases in which the uterus remained retroflexed, adherent and congested. When a retroflexed adherent uterus was left after removal of the adnexa the operation was imperfect.

Dr. Wylie said that the objections to the tupelo-tent were, to his mind, almost as great as to the sponge-tent. The objections to both the tent and tampon were that when they dam up the uterus, when it is diseased, they would bring on a uterine contraction, and if the blood was not permitted to escape through the mouth of the uterus it will make its way through the Fallopian tubes.

Operating Rooms at the Woman's Hospital.—Dr. LeRoy Brown read a paper describing the operating rooms, and the methods used for preparing patients for operation, at the Woman's Hospital (see p. 96).

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NEW UNIVERSITY FOR LONDON—MR. BERRY'S LECTURES ON GOITRE AT THE ROYAL COLLEGE OF SURGEONS—THE BACILLUS OF LEPROSY.

London, July 4, 1891.

The university question in London is again to the front and, thanks to the promptitude with which the Privy Council have taken up the subject, a speedy settlement now seems probable. The scheme for reconstructing the present university having collapsed, the Privy Council are now considering the petition put forward by King's and University Colleges, for the creation of a new university to be styled "The Albert University, of London." The various bodies interested have appeared by counsel before the Privy Council. The medical schools support on the whole the petition of the two great teaching colleges. The Colleges of Physicians and Surgeons are willing to assist if they can have an important share of the management of the new university. Their legal representative tried very hard to show that, because they had some control over medical teaching, they were virtually teaching bodies, but this plea did not appear to find much favor with the special committee of the Privy Council. Lord Selborne, in fact, remarked: "You want to have practically, subject to a veto, the absolute control of the whole thing." The Society of Apothecaries also put in a plea for representation on similar grounds, and if it is granted to the two medical colleges it is difficult to see how the Society of Apothecaries can be excluded. Important opposition also came from the present university; while not opposing *in toto* the formation of a teaching university, it was urged that the words "of London" should be omitted from the title of the new body. Objection was also raised on the part of the present university to a proposition to allow reciprocity with other universities as to terms of residence, while as to medical degrees it was contended that the present university is already in such intimate relation with the medical schools of the metropolis that no new university is needed. As the "medical grievance" is one of the chief grounds on which the formation of a new university is urged, it is rather doubtful whether the Privy Councillors will consider the latter statement with the seriousness with which it was put forward. The Incorporated Law Society urged the formation of a Faculty of Law (in addition to those of arts, science, and medicine proposed by the promoters) and the introduction of a representative of the Incorporated Law Society. The further hearing is adjourned till July 13th, and it was suggested that in the meantime a consultation should take place between the various bodies concerned with a view of some agreement being arrived at.

In Mr. James Berry's recent lectures on "Goitre," at the Royal College of Surgeons, several points of practical importance were brought forward. In discussing parenchymatous goitres Mr. Berry did not speak very favorably

of the treatment by injections and pointed out the dangers of the method and the frequency with which failures occurred. Ligature of the thyroid arteries might be useful in some cases; the most suitable cases in which to employ it were undoubtedly the early cases of parenchymatous enlargement and the so called vascular variety. Division of the isthmus might sometimes relieve dyspnœa mechanically by allowing the two halves of the gland to separate, but it more often did so by draining the gland of its colloid secretion. In many cases of urgent dyspnœa division of the isthmus would not afford sufficient relief. Mr. Berry then discussed extirpation of a portion of the gland. Total extirpation, he said, was not now to be recommended. He then went on to speak of Mikulicz's resection and of the similar operation described by Professor Kocher. Both of these operations agreed in leaving intact that portion of the gland which is nearest to the recurrent nerve. Mr. Berry pointed out that the chief advantages of resection were: 1, That it enabled the operator to remove, when necessary, both lobes of a goitre, and yet leave behind sufficient gland tissue to prevent the supervention of cachexia strumipriva; 2, by leaving untouched the portion of gland covering the recurrent nerve it lessened the risk of injuring the latter. When compared with intraglandular enucleation it had the advantages that, 3, it avoided the severe hemorrhage that often occurred in the separation of the tumor from its capsule, and that, 4, the capsule of functionally useless gland tissue was not left in the wound. Thus the very deep sutures necessary to bring the sides of this capsule into contact to secure primary union might be avoided.

Discussing the operation of removing the thyroid gland, or portions of it, Mr. Berry said the risk of cachexia strumipriva was so great as to warrant us in laying down the law that complete extirpation of a goitrous thyroid gland should never be performed. Cachexia strumipriva had followed partial removal, but the cases in which this had happened had been exceedingly few in number, and in them the symptoms of the disease had usually been slight and temporary. Mr. Berry concluded that, in regard to this, it was immaterial which portion of the gland was left behind. Referring to the treatment of cachexia strumipriva by the transplantation of thyroid tissue into the patient, the lecturer referred to the favorable results obtained by Dr. Bircher, of Aarau. Professor Kocher had also had one very favorable case, the details of which were not yet published. Some similar operations had been performed in this country by Dr. W. J. Collins and Mr. Harry Fenwick, and although the results were not very encouraging, Mr. Berry thought that the information we had on the subject was sufficient to warrant us in giving the method a further trial.

The alleged successful artificial cultivation of the leprosy bacillus opens up a subject of the greatest interest. Until further observations have been made it is scarcely possible to assert positively that there is no fallacy underlying the experiments. It is, however, strongly in favor of the genuineness of the results that two independent workers should have succeeded in their cultivations. Culture experiments are now being carried on at King's College, with some lymph just received from India. Should these also prove successful, and it be found possible to inoculate animals with the disease, the way will have been opened out for a much more searching investigation of the nature of leprosy than has heretofore been found practicable.

They Thought They would Try It.—The inventor of a so-called hair regenerator once sent samples of his discovery, as the story goes, to all the members of the Paris Academy of Medicine. The physicians examined the stuff at one of their sessions and laughed long over the nonsensical preparation. But a few weeks later they whispered to one another, when they chanced to meet: "Do you know, I believe they are growing."

MEDICAL MATTERS IN BERLIN.

LYSOL THE NEW ANTISEPTIC—THE WAY TO PREVENT THE SPREAD OF INFECTIOUS DISEASES IN HOSPITALS—PROFESSOR LEYDEN'S HOBBY ON INFLUENZA—VIRCHOW'S APPROACHING CELEBRATION—PROFESSOR HENOCH HARD AT WORK AT SEVENTY.

[DR. LOUIS FISCHER, of New York, who is temporarily in Berlin for post-graduate studies in bacteriology and children's diseases, sends us the following interesting items regarding medical doings there.—ED.].

BERLIN, June 26, 1891.

THE newest antiseptic in common use here is "lysol," which smells like creoline but is much stronger and makes a lather in a one-half per cent. solution without soap. Several cases of eczema and one case resembling erysipelas have already been developed in consequence of its employment. The nurses complain also of terrible headaches from it. Still in the Kaiserin Friedrich Kinder Hospital, and several other clinics, corrosive sublimate is discarded for the new antiseptic. Carbolic acid, however, is used as before.

I have charge of the Infectious Out-door Department in the hospital named. This is the largest and newest institution of its kind in Berlin, but is not entirely completed yet.

To show you how much we can learn from our German brethren regarding the care of infectious diseases I will have to write in detail.

I will state that, in the first place, there are six different buildings, the largest of which is reserved for out-door treatment, like a dispensary.

Here a young physician has one large room filled with new patients, who must enter here. He examines each and finding a case of diphtheritis, or let me say tonsillitis folliculosis, he immediately transfers the patient to me in room *D*, which stands for Diphtheria. I examine, and if it be a case of diphtheria telephone from my room into station *D*, and the child is retained for treatment.

The House Physician is not allowed to come into my building.

Now if another new case, say a case of gastro-enteritis (summer complaint), comes in, this same young admitting physician transfers it for treatment to the other side of the building where non-infectious cases are treated. I have four large rooms, one is labeled *D* (Diphtheria), the next *M* (Morbilli), another *S* (Scarlatina), and lastly *K* (Keichhusten, or Pertussis).

No mother can come into either of my four rooms unless she passes through an iron gate, which is known as the infectious barrier, and a child with either of the four named infectious diseases is not allowed to be attended in any other room excepting where the name of the disease is treated. Thus the mild out-door cases may be sent home without extra exposure, with rules given them for after-treatment, and the severe ones are retained. We have now seventeen cases of diphtheria, about twenty of scarlatina, and three of pertussis. I am having better results with bromoform here than my predecessor, and only because he used it too conservatively.

Dr. Baginsky allowed me to intubate a child last week in the scarlatina pavilion. It was at the last moment, and death resulted.

In Berlin intubation is entirely discarded and tracheotomy is preferred. They showed me the intubator and extubator and the different cannulas and all are the same as ours, but they try it and all abandon it. This I am told by Dr. Baginsky, to whom I came here with a letter from Dr. A. Jacobi, of New York. Dr. Baginsky is the editor of the *Archives of Pædiatrics*, with Professor Monti, of Vienna, and he also has written a text-book on "Children's Diseases," and is consequently a good authority to quote. He is now busily engaged with his new edition, I believe the seventh, of his text-book, which has lately been translated into French and Italian.

The greatest excitement prevails here in regard to the proposed celebration of Professor Virchow's seventieth birthday, on October 13th next—unlucky number, but lucky man.

At the celebration of his sixtieth birthday about eighty foreign delegates, some from South America, were here in the Rathhaus to the celebration. The next one, the seventieth birthday, will outdo everything Books are being dedicated and golden medals and memorials made, and so on.

About our friend Koch. He is living here in Berlin as everybody else, but nobody thinks of using tuberculin. It is spoken of with disgust, but all speak very highly of Professor Koch himself.

I was shown an article on "Lysol" in the current number of the *Zeitschrift für Hygiene*, edited by Professor Koch, which details the different methods of using lysol, and recommends it as superior to creolin.

It will also interest you to know that Professor Leyden has a hobby, *i.e.*, is almost a monomaniac on the subject of influenza. While I visited him he asked me to tell him all I knew about it, and asked me to write to him about the geographical beginning and ending of influenza in our country.

Dr. Boas, the editor of a text-book on "*Diagnostik der Magenkrankheiten*," has promised to write to the MEDICAL RECORD, once every month, all the latest news in medicine. As he is a collaborator and contributor to the *Berliner Klinische Wochenschrift*, *Deutsche Medicinische Wochenschrift*, and *Zeitschrift für Innere Medicin*, I think you have a valuable acquisition. Dr. Baginsky will also contribute about one or two original articles a year.

It is certainly an encouraging fact for such of our New York men who think of retiring early from work and practice to know that Professor Henoch at seventy years of age lectures three times weekly on his specialty of children's diseases at Charité, and still maintains his position as a leading authority. Thus far certainly he has not outlived his great usefulness.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 12, 1891, *to July* 18, 1891.

PAGE, CHARLES, Colonel and Surgeon. Heretofore assigned to duty in the Division of the Atlantic, will report to the Commanding General, Department of the East, for assignment to duty as Medical Director.

ALEXANDER, CHARLES T., Lieutenant-Colonel and Surgeon. To report for assignment to duty as Attending Surgeon, New York City.

MCCLELLAN, ELY, Major and Surgeon. Heretofore assigned to duty in the Division of the Missouri, will report to the Commanding General, Department of the Missouri, for assignment to duty as Attending Surgeon, Headquarters Department of the Missouri, and Examiner of Recruits at Chicago, Ill.

BROWN, PAUL R., Assistant Surgeon. Leave of absence extended one month.

COCHRAN, JOHN J., Assistant Surgeon. Leave of absence on surgeon's certificate of disability extended three months.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 18, 1891.

ATLEE, L. W., Passed Assistant Surgeon. Ordered to the Independence.

HOPE, JAMES SHIRLEY. Appointed an Assistant Surgeon, from July 10, 1891.

MARTIN, WILLIAM, Surgeon. Detached from duty at the Marine Rendezvous, San Francisco, Cal., and from special duty in that city, and granted leave until September 15th, and then to be placed on waiting orders.

CRAWFORD, M. H., Passed Assistant Surgeon. Detached from the Independence and ordered to duty at the Marine Rendevous, San Francisco, Cal., and to special duty at that city.

ON SYMMETRICAL GANGRENE.[1]

A CLINICAL STUDY, WITH REPORT OF A CASE.

BY ARNOLD STURMDORF, M.D.,

NEW YORK.

THE title "Symmetrical Gangrene" is utilized in the present article, not in Raynaud's sense, in which it has hitherto been accepted, namely, as conveying the conception of an autonomous individual disease—a unique pathological entity *sui generis*—but as a generic term embracing in its designation a multiplicity of pathological conditions, the results of various etiological factors, all, however, presenting certain characterizing features in common—hyperæmia, stasis, or absolute ischæmia of symmetrical parts of the body, usually involving the phalanges of the extremities, more rarely other symmetrically disposed parts, which may result in trophic changes or in gangrene accompanied by certain sensory or motor disturbances.

The elucidation of the pathogeneses of these conditions must be preceded by a careful and systematic separation of them one from the other.

It is only thus that it becomes evident, as we shall endeavor to show, that the many conditions hitherto confounded under the above title, owing to apparent superficial identity of objective manifestations, can, in the light of recent investigations, be recognized and readily differentiated as distinct affections.

The following case, which came under our personal observation, can serve in illustration of a type of this class of diseases:

Mrs. Johanna B——, German seamstress, aged fifty-five, thirty seven years in America, during all of which time she has resided in New York City.

The most searching subjective and objective investigation fails to reveal evidence of constitutional taint, hereditary or acquired, especially as appertaining to the presence of specific, nephritic, neurotic, rheumatic, malarial, or alcoholic tendencies.

Her maternal grandmother died at the advanced age of eighty years, although said to have suffered during life from gout.

Her parents, both of whom are dead—the father, as the result of "heart stroke," at the age of forty-five; the mother, of an unknown illness of four weeks' duration, at forty—had three children. One son, who died of pulmonary consumption, said to have been acquired as a result of excesses in *Baccho et venere*. A sister of our patient, who is living, a healthy mother of five equally healthy children. Lastly, our patient the youngest of the three, whose early history presents nothing of importance as bearing upon her present ailment.

She escaped the ordinary diseases of childhood, and barring an inflammatory eye-affection which developed during her second year, and recurred at intervals over a period of eleven years, she, though never a robust individual, enjoyed comparatively good health and comfortable surroundings.

In her fifteenth year the first molimen menstruale was succeeded by a condition characterized by a feeling of languor or general weakness, paroxysms of severe general headache, and the occurrence of attacks of syncope.

She continued in this state, under medical supervision and liberal administration of ferruginous medicaments, for a period of two years, then recovery gradually set in, resulting in a return of her menstrual periods, which had not recurred after their initial appearance.

The headaches disappeared entirely, but the attacks of syncope persisted to within one year ago.

These attacks would occur from three to thirteen times daily, and last from three to ten minutes. The slighest physical or mental excitation was capable of precipitating them, indeed they often occurred without manifest provocation.

At the age of twenty-one she was married.

In the thirty-four years of her married life she has never miscarried, and gave normal birth to three children, the last nineteen years ago; they are all living, in the enjoyment of excellent health.

As a possible factor in the causation of her symptoms it may be proper to mention in passing that she has never taken any medicine (ergot) during or subsequent to any of her confinements, nor has she partaken of rye-bread in quantities suggestive of a remote possibility of *ergotism*, a condition not unheard of among those of her class.

In her thirty-fifth year she gave birth to her last child, a son. The labor and puerperium were uneventful and recovery complete. Excessive nursing of the robust child during a period of thirteen months resulted in a general deterioration of her health; she became very anæmic and weak, a condition which, in her opinion, resulted in the development of her present ailment. Be that as it may, it nevertheless tends to fix the first development of symptoms as having occurred in 1872, marking the disease as a progressive one of nineteen years' standing, which, as far as can be elucidated, developed in somewhat the following manner:

Without discernible cause, other than that mentioned as alleged by the patient, the integument and underlying tissues of both hands developed, within the space of a few hours, a condition characterized by pain, hyperæsthesia, coldness, rigidity, and violet livid cadaverous discoloration, most marked about the terminal phalanges; from thence gradually receding upward, to merge by imperceptible gradation into the normal condition of the structures above the wrist, which, to all appearances, remained uninvolved. A swelling of the affected parts was not observed. After two to three days this cyanosis of the affected members (Raynaud's "local asphyxia?") subsided in intensity, leaving a mottled condition of the integument covering the distal phalanges of both index-fingers, most intense of the right, resulting from the persistence of dark macules of various diameters, some representing mere dots, others of the size of a large pea.

Gradually coalescing, these spots formed slightly elevated patches of irregular contour and dimensions, dry, horny, and parchment-like to touch, separating after a variable period, with resulting ulcers, which, varying in depth, healed eventually by a dry, tedious process of cicatrization.

Our patient's condition, subsequent to this initial attack, manifested peculiar susceptibilities, both general and local; for in addition to spontaneous recurrences of the cycle of phenomena just detailed, sudden psychical

[1] Case presented at a meeting of the German Medico-Chirurgical Society of New York, December 1, 1890.

impressions, emotional excitation, violent unexpected contact of the fingers with resisting surfaces, in short, the most insignificant mental or physical disturbance, the cooling of the surface of the body or hands, such as would follow the opening of a window on a cold day or placing the hands into cool water, induced an attack of syncope accompanied by a general cyanotic hue of the whole body surface, which, gradually localizing itself in the hands, would then either disappear entirely, the process ending at this stage, or, becoming intensified, eventuate in a renewed destruction of portions of the fingers.

Thus in a period of nearly nineteen years have these attacks of paroxysmal mortification of the fingers and hands recurred innumerable times, at various intervals, and of varying intensity, more severe and prolonged during cold weather, compelling the patient to remain in one room of even temperature.

At times the derma only was involved, the process thus ending superficially; at others, the gangrene penetrated to the very bones of the phalanges, resulting in necrosis, producing indolent sinuses and fistulous tracts through which the dry black sequestra would gradually emerge. When joints were involved, they were totally destroyed.

Even the healing process proved a destructive one, inasmuch as it produced unnatural flexions and distortions of the affected parts, the result of subsequent cicatricial contractions.

Thus we find our patient in a truly lamentable state. Not a single phalanx has escaped the terrible marring of this disease; utterly useless, painful, crippled stumps, mere remnants of fingers upon distorted, shrivelled members, which, to-day, merely bear a resemblance to human hands.

She has wandered about, seeking advice from numberless physicians, been subjected to as many forms of treatment, yet nothing succeeded in checking the terrible malady or in ameliorating her sufferings.

On August 26, 1890, she first came under observation, when we noted the following:

Patient was a woman of small stature, delicate frame, and scanty panniculus adiposus. Marked arcus senilis, old nebulæ corneæ, pupillary reactions normal. Her face is peculiar, presenting the appearance vernacularly termed "hide-bound," the integument being smooth, glossy, thinned, and very tense, like a membrane tightly stretched over the bones, obliterating the natural lines and furrows essential to facial expression, and recalling the condition designated as "La masque sclerodermique." To the touch the epidermis is firm, dry, and almost immovable upon its underlying structures, making it impossible to pinch it into the smallest fold.

On the forehead are plainly visible the ramifications of enlarged and dilated subcutaneous veins; pressure over this region produces slight pitting. There is no atrophy of the facial muscles, nor any demonstrable alteration of their normal volitional or electro-motor status. Examination of the thoracic organs reveals the presence of slight emphysema senilis, otherwise there is nothing to indicate the slightest deviation from the normal. The heart, its valves, and the great vessels do not furnish evidence of disease. Respiration, 22 per minute; pulse, at the radials, 80, isochronous, and of normal calibre and resistance.

Examination of abdominal organs, as of the spinal cord and its reflexes, proved entirely negative. Urine, normal in quantity and appearance, specific gravity, 1.022, acid reaction; no sugar, albumin, casts, or other abnormal ingredients.

Each arm presents upon its upper outer aspect, at a point corresponding to the insertion of the deltoids, a ragged deep scar, penetrating to the bone, the result of suppurating issues artificially produced forty years ago as derivatives, intended to control the chronic inflammatory condition of the eyes mentioned above.

As to the condition of the hands at the time of examination, the accompanying cuts, copied from photographs taken from life by Mr. B. J. Falk, of New York—to whom, as well as to his brother, Mr. J. J. Falk, I would here express my deep sense of appreciation—will furnish such additional features as I may have omitted in my details.

There are, however, certain important features demanding special attention.

In the first place, an appearance which cannot be conveyed by a photographic plate is the peculiar condition of the skin covering the hands.

It is cold, smooth, glossy, thinned, and very tense, similar to, but more pronounced than, that on the face.

In this tense condition the integument stretches over the dorsal surface of the hands to the wrist, where it becomes roughened by numerous fine wrinkles, giving it a peculiar shrivelled appearance, which gradually relaxing from here upward, merges into the soft, lax, normal condition of the skin covering the forearm.

The color of these parts varies, according to temperature or the emotional state of the patient, from a deep cyanotic hue to a grayish white, the terminal phalanges never assuming a normal tint.

A careful study of the numerous solutions of continuity present at this time in their various stages made it evident

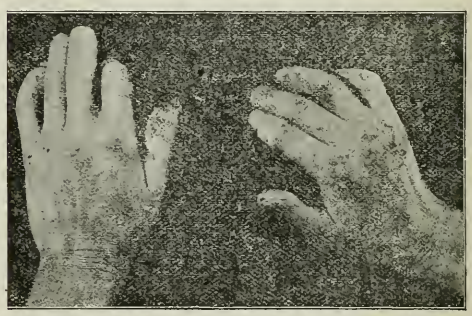

Fig. 1.

that these were the result of different ulcerative processes, some consecutive to others, all, however, the result of perverted circulation. Thus we have, involving corresponding parts of both thumbs and forefingers, the gangrenous ulcers; the dry, shrivelled, mortified tissues have become separated, leaving a moist, yellow, slowly granulating, deep sore, with sloping irregular edges; the lesion in its symmetrical distribution being typical of the disease and well shown in the illustration.

The small round ulcers, seen on the dorsal aspect, over the metacarpo-phalangeal articulations, are the result of the extreme tension of the poorly nourished integument over the prominence presented by the phalangeal ends of the metacarpal bones.

The third variety of ulceration involves previously formed scars. It represents a slow disintegration of the newly formed contracting tissue, the result of perverted nutrition, and is found over the ends of the terminal phalanges. The nails, where present, are thickened, rugose, incurvated, scaly, and brittle. That of the left forefinger is missing, while the one on the second finger of the same hand is represented by a short, thick, narrow, horny stump, jutting backward from the centre of a scar. Hyperæsthesia and pain, although present in varying degrees at all times, become marked only during an attack. Barring these symptoms—which are entirely attributable to the existing tension and ulceration—there are no abnormal sensory manifestations, cutaneous or tactile. Motility of the affected parts may also be considered normal, it being hemmed only by mechanical factors, such as cicatricial contractions and anchylosis, or by hyperæsthesia and pain

on contact, all tending to produce a certain clumsiness in finer motions. Anchylosis is seen between the ungual and middle phalanges of nearly all the fingers. The left index is firmly anchylosed at right angles between its first and middle phalanx.

Careful observation of the patient during a period of nearly seven months does not enable us to add anything of material interest, except that the abnormal tension of the integument is less marked during the intervals between the attacks.

Neither the patient nor her relatives can inform us whether this peculiar condition of the skin antedated or developed subsequently to the gangrene. Thus we have detailed what our observation of the case has elucidated.

Recapitulating, we find a woman of comparatively good family history, previously healthy, although never robust, developed at the age of thirty-five, suddenly, without manifest cause, premonitory symptoms, or constitutional disturbance, a peculiar condition of the hands and fingers characterized by symmetrically located vascular obstruction, accompanied by hyperæsthesia and pain, without swelling. After a few days these phenomena either disappear as suddenly as they came, or, becoming intensified, terminate in circumscribed gangrene, again involving symmetrically disposed areas. For a period of nineteen years to the present time she suffered innumerable recurrences. The attacks vary in intensity and recur at intervals ranging from a few days to several weeks, being most frequent and severe during cold weather. The lesions vary from superficial involvement of the epidermis to the complete loss of a whole ungual phalanx.

Barring a disposition to attacks of syncope, on sudden or prolonged exposure to cold, no symptoms of a constitutional nature are demonstrable.

History.—In scanning the literature bearing upon our theme we find that isolated cases of idiopathic symmetrically disposed gangrene have been recorded as curiosities as early as the sixteenth century.

In the "Ephémérides des Curieux de la Nature," 1685, we find a short description of a case of this nature reported by Christ. Hertius, of Nassau. The "Collection Académique," for the year 1773, contains another example, observed by John and Bernard Schrader in the year 1629.

Boquet [1] mentions a case of three years' standing, in a girl, six years of age, involving the fingers and toes, resulting in total destruction of several ungual phalanges. Later, in the same journal (1830), Moulin reports a somewhat similar case. Joly [2] and Racle [3] describe similar cases, all cited in full in the monograph by M. Weiss.[4]

It were useless to reproduce here the records of these cases, for, barring their historical interest, they are utterly useless for statistical purposes, inasmuch as we look in vain for statements regarding the condition of the internal organs, blood-vessels, urine, and so forth; they are simply incomplete, dry reports, devoid of all *raisonnement*.

The disease was first studied with care by Maurice Raynaud, in his "Thése de Paris," in 1862. He collected twenty-five cases which had been described in detail, or had been personally observed in the hospitals of Paris, and after an analysis of the symptoms defined the disease as "*a neurosis, characterized by an exaggeration of the excito-motor power of the cord presiding over the vaso-motor nerves.*" He interpreted the cyanotic stage as due to a condition of spasm of the vessels, and proposed the name "Asphyxie locale," to designate the peculiar appearance of the parts affected. He also distinguished the resulting gangrene as a form differing essentially from those previously recognized in that it was *not* dependent upon embolism or upon changes of an atheromatous nature in the coats of the vessels.

Attention having been thus directed to the condition, several cases had been reported prior to 1873, when Raynaud published a more complete article on the subject in the "Dictionnaire de Médecine et de Chirurgie," under the title "Gangréne symmétrique." In 1874 he recorded five new cases in the "Archives générales de Médecine," vol. i., pp. 5 and 189, in which, however, the dominant phase, the symmetrical gangrene, was not present, the cases presenting only the cyanotic stage.

Raynaud's deductions and hypothesis as to the nature of this disease, thus based upon an analysis of eight personally observed and twenty-two recorded cases, received universal acceptance, and the condition was then and there established as a definite nervous affection *sui generis*. The literature upon the subject that has accumulated since Raynaud's essay, although not voluminous, is nevertheless quite rich in publications of cases, together with more or less complete articles by observers in all parts of the world. Thus, in France, Hamean and Faure have contributed observations in addition to those of Raynaud.

German literature furnishes articles by Billroth, Ruecker, Fischer, Nedopil, Englisch, and Weiss.

Numerous are the contributions by Scandinavian authors, the most valuable and extensive being those of Schouböe, Weihe, Bjering, Brüniche, Estlander, Holm, Bull, and Nilsen.

American and English essays present, among others, the names of Weir Mitchell, Mills, A. McL. Hamilton, J. C. Warren, M. A. Starr, E. M. Moore, Southey, Finlayson, Fox, and Myers.

A critical review of the publications reveals the following:

Beginning with Raynaud, we find: Number of cases originally collected, 30; excluded by Raynaud as of *doubtful nature*, 6; cases presenting *no gangrene*, simply the stage of cyanosis, *hence not cases of symmetrical gangrene*, 13; *cases unavailable, owing to incomplete data* as to the condition of the heart, blood-vessels, urine, and so forth, 3; cases proven in later stages, or on autopsy, to present evidence of atheroma, thrombosis, or embolism, 5; total number to be excluded, 27. Thus we find that the impressive array of 30 cases gradually dwindles down to a possible 3. Of these 3 cases 2 escaped observation after a very short period, leaving a single case which Raynaud presents as typical. It is as follows:

A married woman, aged twenty-seven, menstruated regularly since her fourteenth year. In February, 1859, four months after her first confinement, she was seized by an attack of paræsthesia, followed by excruciating pain involving the fingers of both hands, whose tips, from looking "dead" at first, gradually merged into a condition of complete black. Now the tip of the nose fell victim to the same process, to be followed, after several weeks, by an involvement of several toes of both feet, as well as the integument of the nates.

At the beginning of April, of the same year, the volar surface of the distal phalanx of the involved fingers and toes, as well as the integument of the nates, presented a number of small superficial sloughs, while the dorsal aspect of the three middle toes showed the integument raised into blebs distended with sanguinolent serum, which, gradually dessicating, left a dry, hard, black scab to slough away.

While the gangrenous process was limited to the superficial layers of the epidermis of the fingers, involving a number of areas, of the size of a pin's head, it penetrated far and wide on the toes, mummifying them, so that by the beginning of June the formation of a line of demarcation was followed by amputation of the first four toes of both feet, resulting in a complete healing without recurrence in any part. Pulse, heart, urine, temperature, as well as all functions, remained normal throughout.

Patient had received one and one half gramme of ergotin four months previously, during her confinement.

The case thus epitomized was presented by Raynaud as one typical of the disease under consideration. In the light of the standard thus established, a careful review of

[1] Journal de Corvisart, xvi., p. 283. 1808.

[3] Gazette med. de Paris, 1859.
[4] Wiener Klinik, 1882.

the accumulated records makes it painfully evident that any attempt at a systematic arrangement or lucid presentation of characterizing and essential features, based upon an analysis of these recorded cases, must prove disastrous; for, barring the unity of the majority of reports upon *the* one dominant phase, *i.e.*, symmetrical gangrene, we find detailed the widest diversity of symptoms, together with the most incompatible and antagonistic conditions—examples of diseases other than that under consideration reported, with incomplete histories and superficial observations, all grouped into this one chimerical category, pervaded by the hypothetical doctrine propounded by Raynaud.

To support this assertion by facts, we will summarize from the literature, in a general way, the cardinal features as observed during the life of the patients, arranging them for comparison and brevity under their respective clinical headings. the information furnished by such few autopsy records as have been published receiving due consideration later.

Sensory Symptoms Recorded.—Pain of varying intensity and duration, generally severe, continuous in some, paroxysmal in others, often localized, sometimes general, affecting the integument only or extending to the muscles and bones; not limited to special nerves in some cases, while in others it follows the course of certain nerve-trunks and their ramifications, the accessible parts of such nerves ("Valleix's points") being sensitive or very painful on pressure.

Anæsthesia recorded in many cases, not mentioned in others, whenever noted it invariably resulted subsequent to the disappearance of pain or hyperæsthesia of the affected parts; thus in one of Raynaud's cases tactile sensibility in both feet was completely abolished, producing the gait and movements of ataxia.

Englisch recorded deterioration of sensibility to mechanical and faradic irritation in one case, while a second one manifested a blunted temperature perception, with complete absence of electro-cutaneous sensibility.

In the case recorded by Weiss, a temperature of + 30° R. was indicated by the patient as hardly lukewarm, while + 40° R. simply produced a sensation of agreeable warmth, differences in temperature ranging from 6° to 8° R. were not perceived.

Transmission recorded normal in some, perverted in others, not observed in many. Thus in Weiss's case the application of a faradic brush or the pricking with a needle produced an immediate appreciation of simple contact, while the characteristic qualitative perception of the nature of the irritant was delayed several seconds. This abnormal state of transmission has persisted in some, disappeared in others; wherever manifest, it developed subsequent to the hyperæsthetic or painful stage of the disease.

Paræsthesia and hyperæsthesia are usually recorded as among the initial symptoms, involving either circumscribed areas or spreading diffusely over the greater part of the affected region.

Motor, trophic, electro-motor, and volitional disturbances, manifested in the muscles, are also recorded in several cases. In both the cases reported by Englisch some of these phenomena were present in a marked degree. In one case the flexor and extensor brevis digitorum of the foot were decidedly atrophied and not responsive to electrical stimuli. In another case the same condition is noted as involving the interosseous muscles as well as the extensors of the forearm. It may be well to mention that in none of Raynaud's cases was this condition investigated.

Another pregnant example of this condition is furnished by Weiss's case, in which during a severe paroxysm there became manifest marked paresis bordering on paralysis, accompanied by rapidly increasing atrophy of the muscles comprising the thenar and hypothenar eminences and interossei of both hands. At the same time the various electro-motor responses became entirely suspended. Petit and Verneuil report complete paralysis of a whole arm in one of their cases.

Vaso-motor disturbances of various degrees are recorded in all cases, as well as symptoms pointing to an involvement of the sympathetic. Thus Raynaud, Schauböe, Bjering, Fischer, and Weiss noted vaso-motor phenomena in the form of circumscribed cyanosis involving the face and auricle, or these parts presented a flushed appearance, accompanied by increased temperature and hyperidrosis, with narrowing of the palpebral fissure, recession of the eyeball, ptosis, and myosis paralytica.

Facial hemiatrophy and aphasia, as well as arthropathies involving various and widely separated joints, are also reported by Weiss; while notwithstanding that Raynaud demands that the lumen of the blood-vessels be free, and their walls in a healthy condition, so that vascular disease, as a causal factor in the production of this affection may be positively excluded, it is not exceptional to find noted general atheromatosis (Verdelle, Bouveret), endocarditis, thrombosis, embolism, malarial infarction (Petit, Verneuil), glycosuria (Fox), nephritis (Debovet), hæmoglobinuria (Myers), acute infectious diseases and fevers (Moore).

Such is the symptom complex found associated with the hypothetical pathogenesis proposed as a basis for the condition under consideration. Can we, in the light of modern pathology, reconcile even a representative minority of the phenomena enumerated to our present conception of a purely functional disorder, *i.e.*, a vaso-motor neurosis? For it must be borne in mind that such is the position defended by Raynaud, who says: "I propose to demonstrate that there exists a variety of dry gangrene, affecting the extremities, which it is impossible to explain by a vascular obliteration—a variety characterized by a remarkable tendency to symmetry, so that it always affects similar parts of both upper or lower limbs, or of all four at the same time, and in some cases also the nose and ears, and I shall endeavor to prove that this kind of gangrene owns for its cause some error as to the innervation of the capillary vessels." [1]

In order to prove that a given condition represents an autonomous, distinct, and special disease, there must first be established the fact that its etiology, clinical history, and post-mortem appearances are invariably characteristic and essentially uniform. How are these desiderata, thus demanded, fulfilled in the present instance?

We have already shown that the cases presented by Raynaud as substantiating, in their leading features, his views of their pathogenesis, contain but a single one which possesses characteristic peculiarities sufficient to claim our attention; but even this frail support of his theories crumbles and fades from the field the moment it is subjected to critical scrutiny, for, like its companions, its ultimate fate is an unknown quantity, inasmuch as we look in vain for details concerning its subsequent developments or final termination.

The same shortcoming characterizes the observations published in the thirty years since Raynaud's original communication, for, excluding all such cases as do not properly belong to this category, nearly ninety-eight per cent. of the patients have eluded further observation.

This in some measure explains the presence of the erroneous and misleading statement in Weiss's monograph, that in seventy per cent. of the cases the attack occurred but a single time. Nor do the records of such few post-mortem examinations as have reached the light reveal a single feature leaning in support of Raynaud's deductions. Here we find everywhere positive anatomical lesions as follows: Wigglesworth, Pitres, Mountstein, Bowlby, Vallard, and Affleck report neuritis, marked and distinct, as the predominating lesion, while Goldschmidt, Ransom, and Barlow found general endarteritis.

Fox, in a supplementary report to a case previously reported as one of Raynaud's disease, says: "Joseph A——, died comatose, with diabetes, albuminuria, and general atheroma of the medium and larger arteries."

It will be claimed by those accepting Raynaud's prop-

[1] Jacoby, G. W.: Medical Journal, 1890.

ositions that functional disorders, as we interpret them to-day, can have no anatomico-pathological basis, and that the post-mortem evidences thus recorded must exclude these cases from the category of Raynaud's disease.

In answer, we would simply point to the nature, gravity, and diversity of the symptoms enumerated to make further argument in this direction superfluous.

As already indicated, the phenomena of symmetrical gangrene are presented by diverse and manifold conditions; nevertheless, gradually accumulating post mortem evidence, in the light of recent advances in neuro- and angio pathology, enable us to group all these conditions under two pathogenetic captions, as follows: 1, Symmetrical gangrene the result of changes in the nervous system; 2, symmetrical gangrene dependent upon disease of the circulatory apparatus.

But before entering upon this classification we must take cognizance of the possibility of ordinary gangrene attacking symmetrically disposed parts, and extending upward in such with a decidedly symmetrical movement. This may be due to the circumstance that both the affected parts have deposits in the arteries in very nearly the same degree—a fact of not uncommon occurrence—and that when gangrene commences in one, the constitutional depression it produces is the determining cause of gangrene in the other.

The causes of gangrene, however, are many, but in one way or another they mostly consist of obstruction or an arrest of the circulation. Still, it is not only the condition of the circulatory channels that determines its production; the cell has a life which may be destroyed by the presence of poisons in the nutrient fluids brought to it through otherwise patent and healthy vessels, producing the various forms of mortification as a result of disordered blood mixtures.

There are, however, certain abnormal conditions of the circulatory organs capable of producing gangrene, whose proper interpretation will go far toward the establishment of a sound pathology for the condition under consideration, transferring it from the position it now occupies among the obscure and little understood pathological curiosities to the rank of common and well known complaints of every-day life.

It is owing to an inherent obscurity in clinical manifestations, rather than rarity of occurrence, that the conditions indicated have not received the full attention and study to which their importance entitles them.

Of these conditions there is one of undoubted existence, even though it does not yet rank among universally accepted entities, namely, cardiac asthenia without demonstrable lesion—the hearts we often find in marantic, neurotic individuals, those frail, sensitive, impressionable creatures who are neither sick nor well, only too often observed in city practice, dragging themselves through a few languishing years to an early grave. They are the thin, pale-faced, prematurely senile people, whose history of suffering begins with life itself and ends with death. How often do we observe this state in infancy; at times as a result of recognizable influences, and again entirely inexplicable.

An interesting study on "Chronic Endarteritis and its Clinical and Pathological Effects," by Dr. A. V. Meigs, published in the MEDICAL RECORD, No. 981, elucidates the subject in hand.

Among the cases cited by this author there is one of an infant between two and three weeks of age, that was deserted by its mother, "having already before this time lost weight and failed in general health and appearance. It was placed in an institution. In spite of all that could be done she soon presented the appearance of marasmus in a most typical manner, and at last, after having for a good while looked like a dried-up old woman, she died at five months of age." Autopsy revealed atheromatosis.

Fig. 2 is a reproduction of the state of the coronary artery.

Commenting upon these cases the author says: "This case may be thought to have been improperly placed in the group, as it was one of ordinary infantile wasting, or, if the name be not objectionable, marasmus, and it presented no unusual symptoms or clinical features; but it has so long seemed to me that there must be some parallelism between the disease under consideration in adults and some of the cases of infantile wasting, that upon finding the pathological lesion so typically developed, I added the case to the group, where, from the pathological stand-point at least, it justly belongs."

We have quoted somewhat at length, even at the risk of prolixity, because we are thus led directly to the consideration of vascular disease as a causative factor in the production of symmetrical gangrene.

Our knowledge regarding the etiology, pathological changes, and clinical manifestations in disease of the vascular walls is extremely vague and limited; and yet, as Meigs says, in speaking of chronic endarteritis, "it is as much of a disease by itself, a separate entity, as are typhoid fever and measles."

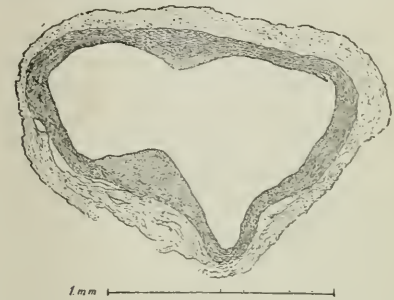

FIG. 2 (× 40 diameters).—The infant was aged five months. This is the left coronary artery of the heart just after its origin in the aorta. The irregularity of thickening is very evident, and it seems equally positive that the process of disease belongs to the lining of the vessel, for the muscular coat is distinctly visible outside of the area of disease, and does not appear to be very much altered, except that in some places the process seems to have invaded it, as well as having produced masses inside the vessel. The plicated membrane is represented by two fine lines with a white space between them, and is visible around the entire circuit except in the thickening, which is represented in the lower part of the picture, where the process of disease has involved the muscular layers to a great extent.

A careful study of this subject certainly reveals the fact that disease of the smaller vessels especially may exist in a degree sufficient to produce most pronounced deterioration of nutrition—even gangrene—without manifesting the symptom complex usually associated with atheromatosis. We have fallen into the habit of excluding disease of the arterial coats when superficial evidences of vascular induration with its accompanying symptoms of disturbed circulation, cardiac action, hemorrhages, variation and absence or irregularity of pulse, apoplexy, arcus senilis, etc., all occurring at a certain age, are not manifest.

Furthermore, the pathology of this condition, as universally accepted, is to the effect that the changes taking place primarily in the walls of the large arteries always spread in a direction toward the periphery.

The case already cited as recorded among others by Meigs, in addition to the following, will prove how erroneous is this belief, for there are cases of vascular disease that present none of these phenomena.

That a chronic endarteritis may start in the peripheral capillaries and gradually involve the whole arterial system, in a centripetal direction, was amply proven by Gull and Sutton.

Later observations by the same authorities on changes in the spinal cord and its vessels in "arterio-capillary fibrosis" tended to fortify their position, which was fiercely attacked by Johnson, Galabin, and others.

Let us see what these conclusions are, what subsequent observation has revealed in their support, and what light they shed upon the pathogenesis of symmetrical gangrene.

In their original communication Gull and Sutton describe an alteration of the arterioles which they call "arterio-capillary fibrosis," in which the external coat of the

arterioles is thickened and has a hyaline or fibroid or hyaline-fibroid appearance, while the capillaries connected with them have a hyaline granular aspect. Only rarely are the intima and the muscular coat thickened, the latter being often atrophied; the lumen is usually narrowed.

They regard this arterio-capillary fibrosis as a disease which occasions atrophy of the surrounding tissues, and usually commences in the kidneys, though occasionally also in other organs.

The resulting contraction of the kidneys they look upon as only a concomitant phenomenon, the essential disease being the affection of the vessels; the clinical history varies according to the organs primarily and chiefly affected.

Thus it will be seen that, according to these observers, the so-called Bright's disease, with contracting kidney, is nothing more or less than a result of this vascular disease.

Meigs, in the article already referred to, differs from Gull and Sutton, inasmuch as he objects to the appellation fibrosis, claiming that it is not a fibrosis in the true sense of the word; but otherwise agreeing and supporting the views thus propounded.

In the same paper the following remarks, which are of interest here, are found: "It is a curious fact, and one worth recording, that in several different sorts of tissue removed by operation by surgeons as incurably diseased, I have found upon microscopic examination precisely the same endarterial inflammation and thickening, in some vessels so great as to entirely close their calibre, as found almost universally throughout the body in the cases of chronic endarteritis or chronic Bright's disease that have been described. These have been ovaries and Fallopian tubes, a vulvo-vaginal retention cyst, a cancerous uterus, and, I think, other tissues. . . ." Furthermore, recognizing the fact that this endarteritus may begin in any organ, he proposes a nomenclature accordingly, claiming that "such name should be modified to meet the needs of individual cases, as the pathological lesion attacks one, or another, or several organs, by saying—chronic pulmonary endarteritis, chronic cerebral endarteritis, chronic cardio-renal endarteritis, or other combinations as may be required to make the name accurately descriptive of the variations of one case from another."

Does it not naturally suggest itself at this stage that this condition may prevail in the regions presenting the manifestations of gangrene, or that there may be some hidden connection between the two.

To illustrate somewhat the clinical aspect of this part of our subject, we cannot do better than to quote a case published recently in a paper entitled "A Contribution to the Diagnosis of Raynaud's Disease," by Dr. G. W. Jacoby, to whom personally, as well as to whose essay, I am indebted for many quotations and points of importance in the literature of the subject, etc.

"A. B—, male, aged forty-two, consulted me first on December 10, 1884, on account of a numbness and coldness of the fingers. Heretofore patient has always been well. He is a hard-working, energetic business man, with absolutely no neuropathic predisposition. His habits as regards alcohol and tobacco are good; he uses both, but moderately. No history of rheumatism, syphilis, or malaria. No history of exposure to cold or wet. He complains that for the last six weeks his fingers have not felt as they should; he thinks that he first noticed the trouble after washing in cold water, when his fingers felt stiff, as though partially frozen. That night he had intense pains in his fingers, and the following morning they appeared swollen and purple, with the exception of the middle finger of the left hand, which looked like dead. This condition has remained almost unchanged; during this time the pain has been continuous, but of greater severity at night, so that it is almost impossible for him to fall asleep. Examination of the patient showed that all the fingers of both hands, with the exception of the thumbs and the middle finger of the left hand, were purplish and cold. To the examiner they felt like ice. This coldness extended upward to above the first interphalangeal joint. The left medius was cold like the other fingers, but differed from them in color, being blanched and dead-like; the thumbs were normal. Sensation to touch and to the pricking of a pin was reduced. Pressure on the ends of the fingers was painful. The pulsation of the radial and ulnar arteries at the wrist was normal in every particular. The feet were cold, but otherwise normal. Heart normal. Urine contained neither sugar nor albumin. Here I would say that the urine was repeatedly examined after subsequent visits, and always with the same negative result.

"During the two weeks following his first visit to me it appeared as though the skin of the fingers gradually dried up, and then from the first interphalangeal joint downward (over the entire cold area) necrotic pieces of skin came off; this necrosis did not extend through the skin, and I can hardly call it a peeling of the skin, as it came off in circumscribed patches which varied in size.

"On the ends of the fingers, upon the palmar side, the necrosis extended through the skin, and black circumscribed sloughs, with a brownish area of discoloration extending around them, were formed. These sloughs varied in size from that of a pea to one which covered the entire phalanx of the left medius. The nails of the fingers showed purple discoloration around the matrix, with disseminated hemorrhagic spots all over. From this history and from the symptoms present at the time of examination I diagnosticated the case as one of Raynaud's disease.

"The patient, not improving under treatment, disappeared from observation until September of the same year. The condition was then as follows: All the sloughs have disappeared, leaving white scars. The entire third phalanx of the left medius is gone, the fingers are still cold and purplish, arteries of the forearm normal, no spontaneous pains, or upon pressure. I have no note as to whether the urine was examined then or not; the probabilities are that it was not, or some note would have been made.

"January 29, 1885.—The patient complains of headaches and various dyspeptic disturbances. He gives a history of several very slight transitory aphasic attacks. An examination of the urine resulted as follows: Light color; specific gravity, 1.010; albumin; kidney epithelia; casts, hyaline and granular. The further history of the case can be told in a few words; it was that of a chronic interstitial nephritis, without any unusual complications. In January, 1886, examination of the patient reveals hypertrophy of the left ventricle, high tension of the arteries, pulse incompressible. In February, 1888, an attack of apoplexy supervened, which resulted in coma and death in four hours."

In commenting upon this case Jacoby says: "This case is not by any means unique, for in 1880 Debove described a case of Raynaud's disease occurring in a patient suffering from a nephritis, and since then Dieulafoy and others have shown that symmetrical gangrene is often observed in conjunction with Bright's disease. The above case, however, acquires great importance from the fact that symmetrical gangrene was present before it was possible to discover any evidence of other disease, the urine and heart having been repeatedly examined."

Closely allied to this form of endarteritis is the syphilitic endarteritis. Syphilis is largely a disease of the vascular system, and it is a matter for surprise that attention has not been directed to the condition of the minute vessels ere this.

That syphilis is one of the causes of chronic endarteritis has long been recognized, but the observations have been principally confined to a study of the condition in the cerebral vessels, and as far as these observations go they only tend to emphasize a single fact, and that is that syphilitic endarteritis runs a more rapid and destructive course than the ordinary form. A study of the cases published reveals that in syphilitic endarteritis we find

either induration of the vascular walls without encroachment upon their lumen, producing transient circulatory disturbances varying in intensity according to the nature and seat of the area involved; or we find complete obliteration of the artery with its concomitant phenomena. The affection, as well as its resulting conditions, is usually symmetrical.

The cases published are those of Duplay, Cabot and Warren, Leudet, Baroux, Brault, Wilks. Ornella's and Schuster's cases closely resemble Raynaud's disease.

This list could be extended, but the following case, cited by Jacoby in the above-mentioned article, will make further testimony or comment unnecessary; it was observed in conjunction with Dr. H. G. Klotz. Its importance entitles it to detailed reproduction.

"C. D——, male, aged thirty-seven, called on me on January 7, 1890. Patient was infected with syphilis seventeen years ago; he gives a clear, subsequent syphilitic history, having been afflicted with various syphilitic manifestations during the three years following the exposure. Since that time, with the exception of an attack of diphtheria two years ago, he has been fairly well. On November 28, 1889, he was exposed to a draught, which was followed by an attack of bronchitis from which he recovered in a couple of weeks. About ten days prior to his first visit to me, upon rising in the morning he noticed that his right hand was cold and swollen, the tips of the fingers having a bluish color and a mottled appearance. At the same time, or a few days later, the left hand became similarly affected, but to a slighter degree. Severe pains in the fingers of both hands then set in; in addition to the pains he also had a feeling of burning and of painful tingling in both hands. The pains during the day were quite bearable, but at night they were so severe that he was unable to sleep.

"Examination shows both hands to be affected, the right one being much more so than the left. The fingers most involved are the third, fourth, and fifth; they are swollen and reddened, with their ends cold and livid. This coldness and discoloration extends upward to the metacarpo phalangeal articulations, but is most marked at the distal ends of the fingers. The difference in the temperature between the ends of the fingers and that of the rest of the hand is exceedingly pronounced; the temperature of the cold parts was not measured, as no surface thermometer was available, but I think that when I say that the difference was at least 10° F., I am rather underestimating than overestimating the condition.

"There is no pain to pressure over any nerve trunk; a small spot over the fourth metacarpal bone of the right hand is quite sensitive to pressure. Superficial anæsthesia is present; pain is experienced when a needle is introduced more deeply. The swelling of the fingers is tense and unyielding. Pulsation is well marked in the radial and ulnar arteries of both hands. The heart and kidneys are normal. The patient, after having been seen by Dr. Klotz, was placed upon a mixed anti-syphilitic treatment.

"January 14th.—Condition slightly improved; swelling not so great. Patient complains now of continuous severe pains in the ends of the fingers. The nails just below their free border show a circle of hemorrhagic spots. The pulps of certain fingers also show spots of hemorrhages shining through the epidermis. The swelling and the bluish color are less prominent; the feeling of cold to touch is now hardly perceptible; the fingers are very sensitive. On the tips some portions are of a white color, suggestive of a flat bulla or blister, covered by a thick layer of epidermis; besides the white spots other portions attract attention, which are of a dark red color, and the tips of the fingers have precisely the appearance as though they had been exposed to severe cold. The general appearance of the patient has considerably improved.

"January 29th.—Decided progress in improvement, particularly as regards the swelling and motility of the fingers; so also are the tips of the fingers much less sensitive; on some portions the epidermis is becoming detached in the shape of hard, thick scales, while on other portions the skin is dry and divided by cracks; some of the tips are hard and calloused. The left hand has undergone the same changes as noted of the right.

"February 2d.—The callosities have gradually concentrated themselves upon the extreme tip of the fingers; then necrosis with formation of new skin underneath has taken place. The fingers to-day are neither swollen nor painful, but the ends are still hard, with necrosed places on each, they look as though they would soon be entirely well.

"May 1st.—Patient has been in Hot Springs, Ark. There he had twenty-four inunctions, thirty-one baths, and two mineral vapor baths. He says that his right hand is an inch and a quarter larger than formerly, which he knows from the fact of being obliged to wear a size and a quarter larger glove than before he was taken sick. The fingers still feel worse when exposed to cold. To-day it seems to me as though the right radial pulsation were not as strong as that upon the left side.

"June 9th.—The iodide which has been taken right along is discontinued; fingers somewhat stiff, but are improved by massage.

"August 5th.—Hands in good condition, although the subjective feeling in them is not entirely natural.

"December 4th.—Hands have normal appearance, but patient still complains of their getting cold very easily. Otherwise they are normal."

Hutchinson advanced the proposition that a syphilitic arteritis may begin in the small arteries of the fingers and ascend, radial pulsation being generally lost after the second attack. He reports a case in corroboration of this view.

Another case, published by Klotz, closely resembles Hutchinson's and is as follows; it is also quoted by Jacoby:

"The patient was a male, aged twenty-five. He was syphilitically infected three years prior to coming under observation; when he presented himself for treatment (February, 1889), in addition to syphilitic ulcers he complained of an affection of several fingers of both hands. The changes in the fingers had taken about a month to develop, and are described by Klotz as follows: 'On examination I found the fourth and fifth fingers of the right hand of a decidedly bluish, somewhat mottled appearance, and distinctly colder than the other three fingers, which presented a perfectly natural appearance. On the affected fingers the free border of the nails appeared remarkably white; next to the free border a zone of fine reddish streaks surrounds the nail, which looks dark blue, like the entire distal phalanx. This color extends over the whole finger, diminishing in intensity toward the knuckles. The fingers are not tender to touch or to pressure. In the centre of the tip, close to the nail, on the fifth finger, the epidermis over a well-defined spot, about the size of a silver five cent piece, is thickened, the surface being brittle and slightly scaling. The fourth finger exhibits nearly the same condition, the thickening of the epidermis only being less pronounced. The other fingers and the hand itself do not show any change of color or of temperature. A similar condition is observed on the third, fourth, and fifth fingers of the left hand, the fourth being less affected than the others. . . . On both wrists the pulse can be distinctly felt, the radial as well as the ulnar, the latter naturally somewhat less distinctly. Neither at the fingers, hands, nor arms can a thickened blood-vessel be felt.' Several attempts were made to measure the temperature of the affected fingers, but without success; it was certainly less than 91° F."

Numerous and valuable observations are contributed to the study of this part of our subject in No. 359 of *Sammlung klinische Vorträge*, by Karl Koch in an article entitled "Die Syphilitischen Finger und Zehenentzündunger."

In this monograph are found a number of personally observed and quoted cases presenting the affection in symmetrical distribution.

Leaving the consideration of vascular disease, we come to the question of anatomical nerve-lesion as productive of symmetrical gangrene.

Here we find that, since the studies of Dejérine and Laloir, in 1881, upon two cases of acute decubitus, where the nerves of the affected parts were found in a state of parenchymatous neuritis, observations are not wanting in number and authenticity to establish neuritis as a potent factor in the production of gangrene. This condition of the nerves has already been alluded to in the pathological reports quoted above, and we may presume to assert that it would hardly be difficult to select cases belonging to this category from among the symptoms enumerated from cases published as examples of Raynaud's disease.

It might be proper to insert here the condition known as "syringomyelia" as related to the above, which is also recognized as producing indirectly gangrene of the extremities, and under which caption most probably belongs the condition of symmetrical gangrene known as Morvan's disease.

There is, however, one condition, obscure in its nature and manifestations, properly belonging to this group of affections, presenting gangrene as one of its symptoms, worthy of special mention, inasmuch as our case probably belongs within its domain, namely, scleroderma.

Although as ordinarily treated of in text books and larger works on skin diseases, no mention is found of gangrene as occurring during its course, an article by H. Senator, in the *Berliner Klinische Wochenschrift*, No. 31, entitled, "Ueber einen Fall von Sklerodermie und Sklerodactylie," presents a case of this nature in which, however, the loss of terminal phalanges was due to a slowly progressing atrophy without suppuration or necrosis.

We find in this article that the first case of this kind was published by Ball in 1871. Following this there were cases published by Charcot, A. Dufour, and Hallopeau. The latter compared the affection to hemiatrophia faciales, and interpreted both conditions as examples of tropho-neurosis with different localization of clinical manifestations, a view shared by A. Eulenburg.

R. Lepine presented a case in which scleroderma, melanoderma and sclerodactilitis were found in conjunction with right-sided facial hemiatrophy.

This and similar cases have led Grasset and Apollinario to the conviction that Raynaud's disease and sclerodactylie are identical.

In this connection the recent reports of Arnozau [1] and Dinkler,[2] are of interest, inasmuch as both found disease of the palmar arches in cases of sclerodactylie.

The occurrence of gangrene in leprosy is too well known to require more than mere mention, while it is essential to include the enumeration of such conditions as Morvan's disease (probably syringo-myelia), a condition described by Dr. Morvan, of Brittany, in 1883, of which several cases have been recorded. A disease which affects the upper, rarely the lower limbs, and is characterized by neuralgic pains, by wasting and anæsthesia, affecting the forearms and hands, and also by what is regarded as pathognomonic—the occurrence of whitlows on the fingers.

As a rule the whitlows appear last, so that as the anæsthesia is already established, they are not painful. Sometimes the first whitlow is painful, while the subsequent ones are not so. There is destruction of the phalanges. Other trophic changes, such as cracks in the skin, deep ulcerations, coldness and lividity of the extremities, with profuse sweating, present themselves, while the nails become shrunken and atrophied.

The condition described by Weir Mitchell as erythromelalgia, consisting of painful circulatory disturbances in the skin of the extremities, as well as the condition known as atrophia cutis, described by Fox, cannot come into consideration, inasmuch as they are not productive of gangrene.

This leaves but one disease to consider in this relation, and that is the process known as white gangrene, about which we find much confusion, with but little information.

It seems to be a special condition of great obscurity as regards its cause, and of great rarity. Very few have ever seen it, but the description of those who have leaves no doubt of its peculiar character.

It appears in early adult life, one attack is usually followed by others; the invasion is apt to occur in the debilitated and ill-fed. An incursion of the affection is preceded by pains in the part, often of a decidedly neuralgic character, and, when in the extremities, extending from the part to be attacked along the nerves leading to the trunk. These pains, accompanied by general depression, may continue for weeks or months before the occurrence of gangrene, which at length shows itself by the formation of circumscribed spots, sometimes including whole fingers or toes; this spot is irregular in outline, with a tendency to become circular and of a dull white color.

The skin soon becomes dry, parchment-like, and somewhat shrivelled, a condition which is retained up to the time of separation of the slough.

The process varies in intensity, as well as in the depth of tissue involved, sometimes destroying the bones.

Thus ends the enumeration of the conditions capable of producing the phenomena of symmetrical gangrene, the consideration of ordinarily recognized causes of mortification being purposely omitted from the text as superfluous.

The review of the condition known as Raynaud's disease, to which these pages are devoted, was not undertaken with any purpose to detract from the true and recognized value of Raynaud's work, which in itself represents but an essential phase in the evolution of the knowledge concerning this condition, which has accumulated since the formulation of his doctrines, and without which the condition might have remained in obscurity; the object of the article was undertaken with wider sympathies, and with an honest desire not to attack the views of another, but to utilize those views for the purpose of bringing the truth to light.

How far we have succeeded in this must be left to the judgment of those capable of weighing the evidence, and that all-potent factor in the solution of vital problems, time.

In closing, we cannot desist from formulating our position as follows:

1. The cases upon which Raynaud's hypothesis were based are valueless, inasmuch as they do not fulfil the conditions demanded for their proper utilization.

2. The clinical histories of Raynaud's cases, as well as those cases published by others, present a symptom complex entirely out of harmony with his deductions as to their pathogenesis, and are easily recognized as belonging to other well-known and established conditions.

3. The post-mortem evidences found by eminent and reliable observers fail to support the views of Raynaud, inasmuch as anatomical lesions are recorded as having been found in the vessels, organs, nerves, or blood.

4 Our modern conception of functional disorder cannot be reconciled with the symptoms and lesions enumerated as occurring in Raynaud's disease.

5. There are conditions capable of producing gangrene, not generally taken cognizance of, whose pathogenesis throws an important side-light on the nature of Raynaud's disease, namely,

6. Endarteritis, simple or specific, may exist in the peripheral capillaries or arterioles, capable of producing the gangrene in question, without presenting during life the manifestations usually regarded as pathognomonic of endarteritis. In view of which,

[1] Congres International de Dermatol. et de Syph., Prog. Médical, ii., p. 162, 1889.

[2] Wanderversammlung der Südwest Neurologen, etc., Berliner klinische Wochenschrift, p. 954, 1890.

7. Raynaud's disease, if it has any existence, cannot be diagnosticated during life; for admitting the possibility of excluding all other conditions capable of producing gangrene, we must yet exclude this form of endarteritis, whose presence could be demonstrated only on the post-mortem table, and whose absence is a *sine qua non* to the acceptance of Raynaud's disease in the sense of its author's conception.

Thus we see that the acceptance or rejection of Raynaud's propositions must rest entirely upon negative evidence of the nature of post-mortem proof of the absence of all anatomical changes explanatory of the gangrene, thus proving beyond a doubt the functional nature of the disorder; and it must be in this direction only that corroborative evidence should be sought and accumulated before this condition can be established as an entity justifying Raynaud's deductions and our acceptance of them.

THE TREATMENT OF CHRONIC RHINITIS

By KARL VON RUCK, M.D.,

DIRECTOR OF THE WINYAH SANITARIUM FOR DISEASES OF THE LUNGS, NOSE, AND THROAT, ASHEVILLE, N. C.

It is not my object to give details of methods to be pursued in the treatment of this affection, all of which are found in current medical literature, but to call attention to an article in the MEDICAL RECORD,[1] by Thomas F. Rumbold, M.D., which, while setting forth some truths, is in my opinion nevertheless misleading, and should not be allowed to go unchallenged, considering its distinguished author and its wide diffusion through the journal in whose pages it appears. Dr. Rumbold's paper purposes to set forth five causes for failure to cure chronic rhinitis, the first being defective instrumentation, especially defective tongue depressors, manipulated by the physician instead of by the patient. No one will gainsay that a tongue depressor about six inches long and two wide, to go between the patient's teeth, is an unsuitable instrument, and any intelligent physician would prefer to such a one the handle of a spoon, until he could get what would answer his purposes and convenience. The author, however, carries the idea that with a suitable instrument, held by the patient himself, inspection of, and local application to, the naso pharynx can easily be made. While true in some cases, it utterly fails in *the great* majority, especially if the inspection is to be a thorough one, or the manipulation with instruments requires to be more than momentary. In such cases the soft palate must be held away from the posterior wall by one of the usual methods, in order to accomplish our object. That in cases where we succeed, any advantage is derived by having the patient hold the depressor, I think is erroneous; in my experience the attempt was, as a rule, unsatisfactory, and the physician's holding his depressor, placing it properly, and exerting gentle pressure in the proper direction, can hardly be classed as a cause for failure to cure the disease; indeed, any physician could get along with a spoon, if he had to, and yet cure a case of chronic rhinitis.

The second cause for failure, the author sees in the use of watery sprays, or cold fluid vaseline sprays, instead of warm vaseline sprays.

I would humbly offer the opinion that all, excepting perhaps the mildest, cases of chronic rhinitis are incurable by sprays of any description, not excepting warm vaseline. Temporary benefit may, and frequently does, result from such treatment, and I have obtained such results from the most varied applications, warm or cold, and seen it even from salt and water snuffed up by the patient, and the use of various snuffs, powders, and ointments. In the light of my experience failure to cure is not due to the particular kind of spray, but to the fact that physicians place faith in these as a curative agent.

[1] Issue of November 23, 1889.

The third reason for failure Dr. Rumbold sees in the use of compressed air apparatus, operated by pump of brass with leather piston lubricated with oil, furnishing a bacteria laden air, the bacteria being derived from decomposing lubricants and decomposed animal tissue, *i.e.*, the leather packing; he also holds responsible the undue force with which the sprays are projected against the patient's tissues, and would have the pressure just so much for one purpose and more or less for another, etc.

While I do not pretend to say how filthy compressed air-tanks and pumps may become, I nevertheless maintain that an oiled surface cannot give off bacteria to the surrounding air; also that leather is not necessarily decomposing animal tissue. I have however made a careful examination of my air-pump, and subjected the air from my receiver to the proposed test, with negative results. To prove his position the author must show, not only that bacteria are found in the receiver or air-pump, but also that they are pathogenic; he must show that the air with which he filled his receiver did not contain them. As to the relative amount of pressure employed, I take it that enough to properly work the spray apparatus is sufficient and answers every purpose, and I think the author can satisfy himself that the pressure indicated by the gauge of the receiver bears no relation whatever to the force with which the liquid is projected against the patient's tissues. Neither do I approve of the use of the spray for the purpose of blowing the secretions out of the nose or throat, as Dr. Rumbold proposes, but chiefly as a cleansing wash, by which the secretions find exit through the natural channels by gravity. For the same purpose powders are occasionally useful by stimulating the natural secretions, and thus exert a depleting as well as cleansing effect. Another cause for failure the author sees in comparative insufficiency of the instrumental outfit of offices where nasal disease is treated, and he compares the physician who has not an elaborate outfit to the merchant who attempts to do business without a proper stock in trade. I, for my part, would fear more for the patient in the hands of a physician whose stock in trade consists of numberless instruments, elaborate apparatus and appliances, instead of proper knowledge, keen perception, and experience, than for him who is treated by a physician whose stock in trade is chiefly "brain," and who may find it entirely unnecessary to equip himself with anything but the simplest devices and instruments for his work.

The fact is that the armamentarium for the treatment of common nasal affection is not necessarily complicated or expensive, a fair and convenient outfit need not cost more than $50 or $75; unless, for greater convenience or elegance, we want fine operating-tables or stands, expensive illuminating apparatus, electric motors, air-tanks and pumps, etc., all of which can be dispensed with without disadvantage to the patient in his prospect for a cure. Even a specialist will get along nicely with an outfit that he can carry in his pocket. Indeed, the simpler the apparatus the better work we can, as a rule, do with it, and it is in better professional taste to avoid all showy apparatus. I conclude, therefore, that the cause for failure in curing chronic rhinitis does not lie in any of the first three points made by the author, but is more likely to be found in his fourth and fifth causes, namely, insufficient anatomical and physiological knowledge on the part of the practitioner; and although I agree with him in this respect, I do not believe that the form of treatment he objects to as faulty from this cause is necessarily so, on that account, nor that his criticisms are all justifiable. Indeed, I find that some of the best authorities conflict seriously with the author's views on etiology, which although not distinctly expressed, he seems to hold. Thus he, for instance, complains of the initiative correction of partial or complete nasal stenosis in the beginning of treatment, and to the removal of hyperplastic tissue; he believes in "taking cold," and the use of tobacco or alcoholic liquors, as the chief etiological factors of chronic rhinitis, a position he could not main-

tain in the present light of our knowledge. He complains of scar tissue as occurring in the nose after operations, and its interference with physiological functions, but he utterly fails to give us a glimpse of his views as how these functions are to be restored in chronic rhinitis with stenosis and hyperplastic changes, without operation, unless he accomplishes all that with sprays of warm vaseline.

The author justly urges the importance of hygienic and sanitary measures, without which the most painstaking treatment will be greatly hampered and relapses after cure will be more numerous.

In conclusion, I desire to say that it is not only the specialist who can successfully treat chronic rhinitis, but the general practitioner also, if he will, by painstaking study of the cause, thorough examination and diagnosis, furnish himself the indications to be fulfilled in a given case. To be successful, however, a free and unobstructed passage for the air through the nasal passages must be secured, which, unless in the mildest cases, cannot be accomplished with medicaments in the form of sprays (watery or of vaseline), or powders, but requires operative interference. The success does not entirely depend upon the peculiar method by which we overcome the obstruction and secure patent nasal passages, be that by chemical or galvano-cautery, saw or knife, snare or écraseur, but upon the efficiency and permanency with which it is accomplished by the agents employed. Much is to be done in the after treatment, in which sprays, especially of warm vaseline, serve a useful purpose, as do also proper care of the skin, and other hygienic measures, the correction of digestive derangements, etc.

Asheville, N. C.

INJURY TO THE THORACIC DUCT, WITH AN UNIQUE AND INEVITABLE DEATH BY INANITION.

By ALVIN EYER, M.D.,

CLEVELAND, O.

December 17th last, Charles G. S—— was admitted into Lakeside Hospital with the following history: Railway brakeman, aged twenty-eight, with good general health up to the previous day, when he met with an accident, the following report of which is as complete as could be obtained. By the slipping of a "push pole" (a pole attached by one end to an engine and used in moving cars) he was so caught as to be squeezed against the foremost car and bodily rolled out from between the two. When picked up he was found several feet from the train and in an unconscious state.

Upon being brought some thirty miles an examination brought to light little beyond severe localized pain in the right lower chest with some considerable injury to the right forearm, and a distinct band of discoloration some four inches in width, encircling nearly the entire abdomen. While no crepitus was found it was still thought best to firmly strap the right chest as a precautionary measure against possible fracture of one or more ribs. This, with attention to the injured arm and such anodyne treatment as was required, was all that was deemed necessary for the time being. In the course of twenty-four hours, however, there was a rise of temperature and upon auscultation evidences of pneumonia, corresponding to point of injury over right lung, were plain. He was at once placed upon additional treatment, and for the next sixteen days seemed to run a favorable, yet perhaps severe, course of traumatic pneumonia involving the entire lung.

Beyond somewhat more pain than one generally observes in such cases, however, nothing unusual presented itself, except on the second day, when there appeared a gaseous distention of the abdomen and also enough dyspnœa with a hyper-resonance of both lungs to suggest pneumothorax; but whether pneumothorax actually existed or whether this condition depended upon the abdominal distention was not definitely determined at once and in twenty-four or thirty-six hours the whole chain of symptoms, in so far as the thorax was concerned, passed away, leaving the patient about as before with the exception of more or less constant abdominal tympany.

On the seventeenth day there came a great and most remarkable change over our case. Pain was complained of, and upon examination some redness with soreness upon pressure was found directly above and somewhat behind the anterior superior spinous process of the right ilium. Upon deep pressure fluctuation could be obtained; and after the introduction of an exploring needle, an opening was carefully made quite down upon the external oblique muscle.

The moment the fistulous tract was struck there came a gush of most offensive gas, followed by a flow of nasty-smelling discharge, not unlike fecal matter both in appearance and odor. So offensive was this discharge that the patient had to be removed from the general ward into an apartment by himself. An intestinal fistula was at once thought of, and in the next day or two, with the opening still discharging a fluid very similar in appearance to what was given him to eat (expressed beef-juice, milk, and whiskey), and with repeated assurances of the orderlies that its odor was identical with what had passed per rectum, the diagnosis of such a fistula confirmed itself in our minds without further or special investigation.

After two or three more days the discharge lost its offensiveness to a very great degree; but otherwise remained much the same—opaque and milky—with marked increase of flow at any time the patient was asked to bear down as though at stool. At this time, too, rapid emaciation set in, and from these two facts—loss of odor and the unusually rapid emaciation—it was inferred that the intestinal lesion was high up and the food-stuffs given him came away as chyme. Under this belief it was deemed best to limit stomachic alimentation, as to quantity, and confine it entirely to predigested nitrogenous foods, while rectal feeding was pushed to its utmost limit Notwithstanding, however, this forced feeding and the apparent well-doing of his pneumonia the patient was still rapidly succumbing to starvation. So rapid was his inanition that it was estimated his body loss—from the date of fistulous formation (seventeenth day) to death (thirty-eighth day)—exceeded four pounds per diem, and that his entire loss much exceeded one-half his normal body weight.

During all this time we could see nothing to be done, more than sustain strength and life until such time as the patient's pneumonic condition would permit a restoration of the intestinal continuity, keep the tissues of the right side well open to favor drainage, and prevent sloughs. Starvation, however, went uninterruptedly on, and as already stated, death supervened on the thirty-eighth day after injury.

This, then, briefly stated, covers the history, clinical course, diagnosis, and fatal ending of our case. To sum up its clinical significance we will take up: First, our diagnosis, not in its entirety, but only in so far as the fistula was concerned; second, the autopsy and its findings; third, a study of the case, upon the whole, with the view of establishing a differentiation between fistulæ communicating with the thoracic duct, and such other fistulous tracts as may prove undefined or doubtful as to origin.

1. In defence of our diagnosis of intestinal fistula I will only say: In the sixteen days' observation of the case there were, with but three exceptions, absolutely no indications of disease or injury other than those referrible to the right lung—now in an advanced stage of pneumonia.

With the appearance, therefore, of the painful bulging, followed by the rush of gas and fluid upon lancing, which plainly established the existence of some form of fistula,

the exceptions—a band of discoloration, obstinate bowels, and slight tympany—were recalled; and, for the life of me, nothing could have been plainer or more easy to diagnose.

In fact, the whole case seemed too plain and simple to be mistaken. The gas and decidedly fecal smelling discharge in themselves moulded at once our belief, diagnosis, and mistake. That there was a fistula was plain; that it was fecal was too plain, and there we rested.

To give you the benefit that was given the House Staff, let me tell you, as was told them, how all this chain of occurrences happened:

"You see this man was caught between the end of a pole and a box car; the little black and blue band about his waist plainly indicates to you what part of the body was caught. Now the pole must have so squeezed the abdominal parieties up against the car, as to impinge a knuckle of gut within its embrace; and while this did no immediate or serious injury to the belly or its contents, there still must have been enough harm done to subsequently set up a low form of plastic inflammation whereby the gut and peritoneum became agglutinated and adherent one to the other.

"In due time, of course, death took place in that portion of the gut and the delicate serous membrane which was most centrally located in the adhesion, and then the tissues gave way and the fistula became established. Of course it could not communicate with the abdominal cavity, because you see the opening through the gut and peritoneum was simultaneous; and as the healthy portions of the two are still adherent there is a sort of artificial anus formed, and through it, of course, the fecal matter must pass, then force its way on through the extra-peritoneal tissues in whatever direction it finds least resistance. Observe as you make pressure on this side a wave appears on the opposite side, not far underneath the skin, and beginning evidently in the linea alba. That is the fluid coursing its way through the newly made channel toward its outlet.

"As to what can be done in such cases, for the present we will only make a freer opening, so as to give free vent and prevent the burrowing of fluids and subsequent sloughing. Later on, of course, when his pneumonia has subsided, laparotomy with, perhaps, enterectomy, will be performed, all of which will be a simple matter.

"Stimulate and feed him well, for, as you see from what has been said concerning the character of the discharge, which really seems to be nothing more than partially digested milk, whiskey, and beef juice, the lesion must be high up, and therefore the area for absorption is greatly cut off.

"The discharge which, you will remember, was so very offensive no longer smells badly, which also means that the foods leave the canal high up, and therefore have no chance for decomposition.

"This without doubt would be a nice case for Senn's hydrogen gas test, but, as the case is so plain and the poor fellow has already been badly hurt, we will pass that by. The pneumonia, of course, is a contra-indication for the use of an anæsthetic, so all we have done, as you know, had to be done under the local spray and cocaine, neither of which is very eflectual."

These, in substance, were the clinical points upon which was based our diagnosis two days after the fistulous formation. From then on the patient's pneumonia did well and seemed promising; and so was also our forced feeding borne well by him, but he starved to death on the thirty-eighth day, and thus ended our first lesson.

Autopsy.—In making the autopsy it was at first determined to follow the tract from without in, but as it proved to run an unfavorable course for such a step, the attempt was abandoned and the abdomen gone into through the linea alba—the incision extending from the ensiform cartilage to the pubes. At first glance there could be seen many evidences of starvation's fearful ravages. All the viscera presented an unusual dryness, with the surface of the intestines and liver much darker in appearance than normal. The gall-bladder was greatly distended and seemed on the point of bursting; while the omentum, always so rich in fat, was but a mere network of blood-vessels and connective tissue. These points being noted the point of "adhesion" was at once looked for, but no such condition could be found; and then a search for the fistula began. For this we looked high and low. Applying a double ligature just above the sigmoid flexure and dividing the gut between the two, we emptied the abdomen from below up, carefully noting every pathological change as we went.

Up to the diaphragm we failed to find even evidences of inflammation, new or old. In fact, the abdominal cavity seemed absolutely free from pathological conditions, and after going over the intestinal tract again and again, we thought it possible that the œsophagus might be the seat of lesion. So accordingly the liver and pancreas were removed and the diaphragm, beginning at the œsophageal opening, slit up to the ensiform cartilage.

In removing the liver from its lodgment it was observed that it was adherent to, and much softened about the aortic opening in the diaphragm, with evidences of recent inflammation, and several masses of a cheesy deposit, not unlike the residue of partially digested milk in appearance, embedded in its upper surface. The diaphragm up to the œsophageal opening also showed the same evidences of inflammation, and at this latter point the bands of muscle forming the opening were so adherent and matted to the gullet that, in separating and lifting the latter out through the cut made in the diaphragm, it was so torn as to prevent us from determining whether its destruction had been ante-mortem or made by us. From the character, however, of the blackened and broken-down tissues, not only of the liver but the diaphragm and œsophagus, and our failure to find any other lesion, we momentarily concluded we had reached the seat of trouble.

The sternum and cartilages were next removed and after carefully examining the diseased right lung, which was found in various stages of hepatization, the same was lifted out of the thorax, and the upper surface of the diaphragm about its openings further examined. Its condition was similar to that found below, except, perhaps, that the inflammatory process had not been so extensive. The gullet above this point was also further examined but found to be perfectly healthy. Upon complete removal of the lung from the chest there was discovered a bulging into the cavity, from the back and uppermost point of its apex, which upon more careful investigation was found to be a post-pleural collection of fluid. Upon tapping its sac this fluid seemed to be identical with that which had been making its escape per fistula during life, and further examination proved this finding to be correct. The pent-up fluid was our supposed chyme, and had burrowed its way between the pleura costalis and chest-wall by gravity while the patient was flat upon his back. A careful dissection also proved the incorrectness of our just-formed belief that the lesion could have been in the œsophagus at the point of opening in the diaphragm, for in no way could that tear and the newly found cavity be made to connect. This discovery, then, put us entirely at sea, and it was not until the bulging pleura was again referred to and its contents found to consist of a rich creamy clot, overrun by a brownish liquid, that a chyle-clot and lymph were thought of.

Specimens were at once examined by heat and the microscope. The former clearly proved the fluid to be pure lymph, while the microscope showed us a collection of the most beautiful specimens of chyle-corpuscles ever looked upon. Thereupon the autopsy was brought to a speedy end by going directly into the posterior mediastinum, and but little deeper than we had gone for the gullet, where the hard-looked-for hole was found—not in the alimentary canal, however, but in the thoracic duct. It was through this hole, then, that all our endeavors for the poor fellow's life had slipped. The fistula was found

within the very opening formed by the diaphragm for the tube's reception, and the diaphragmatic crura, fasciculi, and interdigitations surrounding it likely had much to do with its formation, and probably led to the division of the stream of chyle, directing the one into the thorax and the other through the muscles of the back and abdomen to its ultimate point of outlet.

Points of Differentiation, as presented in this case, bearing directly upon the non existence of intestinal fistula, and somewhat plainly indicating division of the thoracic duct.—Under this head comes, first in order, Senn's hydrogen gas test. Had this test been applied, without doubt its results would have led to such further investigation as would have ultimately led to a correct diagnosis. Second, heat test and miscroscopic examination of fluids discharged. Had the former test been resorted to, these would surely have followed and a correct diagnosis might possibly have been arrived at. Third, shortness of inanition period. This, it would appear, should prove, in an otherwise healthy subject, a strong and emphatic diagnostic point indicative of thoracic duct destruction.

The adult subject, it is well-known, succumbs to starvation in twenty to twenty-four days; but the phenomenon generally takes place under the withdrawal of all nourishment. Here, while the subject was suffering from pneumonia, and was supposed to have an opening near the stomach through which his food escaped, death still came entirely too soon; for under the forced rectal alimentation, life should have been maintained for many weeks longer, had the fistula been elsewhere than in the thoracic duct.

Comments Worthy of Record.—In endeavoring to arrive at the probable cause and time of lesion, which it seems to me would be of interest to know, two questions put themselves: Was it the destructive outcome of existing inflammation and formed on, or about, the seventeenth day? or, Was it purely traumatic and formed on the day of original injury? The inflammation about the aortic opening in the diaphragm and adjoining structures, as found in the post-mortem examination, with the intervening sixteen days before the fluid came to the surface, combined with the terrifically rapid emaciation after the seventeenth day, would all speak strongly in favor of the first proposition.

In my judgment, as formed from a careful noting of the entire case, however, it would be under the latter proposition that the actual cause and time should be placed. In support of this, I would argue that the division was sustained in the accident, but happened to be so located within the grasp of the tendinous arch, thrown from one crus of the diaphragm to the other, that immediate, continuous escape of lymph was checked, and the chyle-clot (found upon the removal of the liver) allowed to form in the tissues about the lesion, and so pack and arrange itself there as to temporarily dam up the break. I believe this condition to have existed up to about the sixteenth day, when the inflamed tissues gave way and the burrowing of chyle began.

The main point in support of this theory is to be found in the peculiar tympany appearing on the second day after the injury. The distention, which was not only peculiar in its mode of coming but remarkably so in its stay, could not, at the time, be accounted for. The symptom proved unusually distressing, because of the existing pneumonia, and in our efforts to dispose of it full doses of salts were given, but to no avail. While the bowel discharges were copious and watery, the tympany still remained. This, it now seems, must have depended upon the gas being in the peritoneal cavity, and not in the intestines; and from its existence and its time of existence I infer it to have been a phenomenon coincident to the injury to the duct and also, therefore, a data fixing the time of said injury.

As to the cause of such an injury one could hardly conceive its possibility. Whether compression of the lower abdomen could so forcibly crowd its viscera against the diaphragm and upon the, perhaps, well-filled, duct, as to injure it; or whether the squeeze to the chest could have caused such forced respiratory efforts as to produce it; or whether an over-excited diaphragm could cause it by its muscular contractions, are only possibilities to be conjectured, but not shown. How this tube, lying as it does between the aorta and vena cava, could be singled out and divided by causes either indirect and inflammatory, or direct and traumatic, without also tapping one or the other of its fellow companions, seems to us as incomprehensible, in the study of nature's method of applying her causes in obtaining her effects, as does it seem irrational that she should assign to this poor mortal a death so sure, yet indirect and terrible, as starvation, when she might as well have decreed the tapping of either one of said vessels and let forth his simple life in a single moment, without bodily pain or mental suffering.

It will be observed that in the autopsy no evidences of inflammation were to be found other than those in the lung, diaphragm, and the structures immediately adjacent to its aortic opening. These, of course, must be regarded as entirely traumatic. The post-pleural cavity, containing at least two pounds of chyle, with the channel leading to it from the point of rupture in the duct, and also the upper two thirds of the tract through the extra-peritoneal tissues, were as free from inflammation as though nature had formed and lined them. This latter condition, which positively demonstrates the non-irritability and homogeneousness of chyle to the textural structures of the human body, suggests two points of interest.

1. Could the chemico-physiologist ever be enabled to elaborate out of food stuffs a product identical with that made in the human digestive laboratory then it would appear the surgeon's skill and ingenuity might lead to some form of venous feeding whereby life might be indefinitely maintained.

2. Bearing upon the much-discussed question of asepsis versus antisepsis the case in point furnishes much practical information favorable to the former theory. Here existed a collection of chyle, pent up between delicate and sensitive tissues for a period of at least sixteen days, without the slightest evidence of inflammatory irritation. Had it been bile, gastric or pancreatic fluid, or even blood, surely no such inaction could have been expected. Upon what, then, could this difference depend other than the possession by the four latter fluids of materials septic to the body tissues, on the one hand, and the asepsis of the sterilized chyle, by virtue of its digestion, on the other? The mechanical irritation, by contact, of this fluid must certainly be as great as that of sterilized water by boiling at blood heat; and therefore it would appear that the aseptic condition of the surgeon and his materials in use should become in the end practical, and by all means preferable to the dangerously potent antiseptic remedies used as germicides.

89 Euclid Avenue.

Service of Legal Papers upon Insane Patients.—At a meeting of the State Commission in Lunacy, on June 2d, the following orders were adopted: 1. That the superintendent or officer in charge of each institution for the care and treatment of the insane be directed not to permit the service of any legal process whatever upon any insane patient, except upon the order of a judge of a court of record, which shows that the judge had notice of the fact that the person sought to be served was at the date of the order an inmate of such institution. 2. That no insane person be permitted to sign any bill, check, draft, or other evidence of indebtedness, or to execute any contract, deed, mortgage, or other legal conveyance, except upon the order of a judge of a court of record, which shows that the judge had notice of the fact that the person whose signature is sought to be obtained was at the date of the order an inmate of an institution for the care and treatment of the insane.

A CASE OF CÆSAREAN SECTION.

By HAL C. WYMAN, M.S., M.D.,

PROFESSOR OF SURGERY, MICHIGAN COLLEGE OF MEDICINE AND SURGERY, DETROIT, MICH.

On the evening of January 19, 1891, I was summoned to attend Mrs. J——, and perform the operation of Cæsarean section. Professor Dayton Parker was in attendance, with the family physician, Dr. McPherson, and after consultation they decided that the operation afforded the only chance for saving the lives of the patients. Professor G. W. Stomur and Dr. Newman were also summoned to the case. The lady was a primipara, who had been married ten months. She was of robust figure, and when standing presented an unusual prominence of the abdomen for a pregnant woman.

Her mother said she had always had a large stomach, and she thought it was caused by being run over by a wagon when she was about seven years old. She had had no severe illness, and was cheerful and hopefnl, as women of her age are.

The largest circumference of her abdomen was forty-eight inches. The external genitalia were normal. The inferior strait of the pelvis was normal, and the pelvic canal gave no suggestion of lack of capacity as far up as the finger could reach. She called in her family physician three days before the operation, because of bearing-down pains and apprehension that labor was about to begin. He examined and found the os undilated but flattened, and from the patient's description thought her pain was due to approaching labor. He explained to her that the first stage of labor in first confinements was often slow and tedious, and that it taxed the patience of the patient to the utmost. He left her, with instruction to call him if the sufferings increased or the pains became more frequent. He heard nothing more until the next day, when he visited her and found that the pains had been less frequent and urgent in their character. He examined again and found the os had not changed materially from the condition he had observed the day before, and he left her with the impression that the case was one of "false alarm," and that she might go a week or more before being again disturbed. The next day he was called again. The pain had increased in frequency and severity. He found no material change in the os from what he had found forty-eight hours before. He remained with her a couple of hours and made frequent observations during the pains. He observed the os flatten out and dilate during a pain; could feel the fœtal head pressing against the membranes, and thought that the case was one of simple tardy dilatation. He saw her again in the night, and the condition being practically un altered gave her a fourth of a grain of morphine to relieve her distress and hasten the progress of the case. She became comfortable under its influence and he was not called again until twelve hours later. He now found her suffering more severely than before. The pains were regular and forceful. The os had dilated to the size of a quarter, and the doctor expected to complete the labor in a couple of hours. Stimulation of the os with the finger increased the violence of the expulsive efforts, but the head did not advance. By conjoined manipulation with the left index-finger in the vagina, and the right hand over the abdomen, he found the left parietal eminence of the child presenting, and thought the head was prevented from engaging at the superior strait by resting too far forward over the symphisis. He then endeavored by conjoined manipulation to cause the head to descend, and introduced his hand into the vagina the better to manipulate. He now learned that the last lumbar vertebra was thrown forward on the sacrum until it approached within two inches of the symphysis pubis. It was clear that labor could not be accomplished by natural means. He tried forceps, called counsel, and trie l to flatten the head so that it would engage. On either side of the projecting vertebra the pelvis appeared roomy enough, and there was no trouble in introducing and applying forceps but they could not be thrown far enough forward to grasp the head so that they would not slip off. Dr. Newman, who had a very small hand and arm, thought he could perform podalic version with advantage to the patients, but he did not succeed. The feet could not be brought down. Cæsarean section was now the last resort. She was placed on her back on a table, the abdomen was thoroughly washed with corrosive sublimate solution, after having been first cleansed with soap and water. It was dark and lamp-light had to be used. An incision, commencing two inches above the umbilicus, was carried down to the pubic symphysis. The abdominal wall was quickly divided, care being taken to secure all bleeding points with catch-forceps. The uterus rose into the wound and was kept in contact with it by pressure made on the outside of the abdomen by Professor Stomur. The finger was run over the presenting womb to determine the attachment of the placenta, which was found over the left cornu. Incision was made through the uterine wall, about five inches in length, and the fœtal head was at once extruded. Grasping it with my hands the delivery was soon completed. The placenta followed immedi ately. Very little hemorrhage came from the uterine wound, and the contraction of the organ was uniform and rapid. Not once did the intestines appear in the wound, so evenly was the pressure applied to the abdominal walls. The uterine wonnd was closed with interrupted sutures, nine in number, half an inch apart, and passed deep enough to embrace the whole thickness of the muscular wall of the womb. At the lower angle of the wound near the uterine cervix an irregular transverse rent was found at a point where the uterus had been greatly thinned by the pressure of the head. This required to be closed with three extra sutures. The uterine peritoneum was very lax, and by means of interrupted sutures was drawn carefully together over the uterine wounds, entirely separating them from the abdominal cavity, which was now carefully cleansed of bloody fluid which had apparently escaped from the rupture found at the inferior angle of the wound. It was closed by interrupted sutures embracing all the tissues of the abdominal wall, including the peritoneum. A dressing of iodoform and cotton, fastened with a bandage, was applied, and the patient put in bed. When the operation was commenced her pulse was 120 beats per minute, and her temperature 101° F.; when it was concluded pulse frequency was reduced to 98 beats per minnte, and temperature remained the same. Dr. Newman made valiant efforts to induce vigorous and permanent respiration in the infant, but without success. The patient died forty-eight hours after the operation, of pulmonary œdema and cyanosis, the result of exhaustion of the right heart, due to the protracted labor. No autopsy was permitted, but the patient presented no signs of repair. Her bladder and bowels acted normally after the operation. In presenting this case I am reminded of the splendid achievements in Cæsarean section published by Professor Howard Kelly of Johns Hopkins University, in a recent number of the *New York Medical Journal*. His cases were all successful, and the operations were performed with neatness and despatch, as indicated by the stop watch record of the "time" from start to finish. Whether any of them had been as long in labor, and had had as many futile attempts at delivery as my case, I do not know; but, while the value of rapid execution in the performance of this operation cannot be easily over-estimated, I believe there are possibilities in the history of the cases which will make Cæsarean section generally an operation with serious mortality.

The danger of not recognizing the condition of the patient until she is exhausted by heart-strain is liable to occur. In my case there was nothing presented to the family physician of an unusual character until the hand was introduced. She was neither a cripple nor a dwarf among the people who saw her every day, so there was

nothing to make the doctor apprehensive except the pro tracted and violent character of the labor, and that was not unusual for a woman with her first child. As to the time, indicating the rapidity with which the operation was performed, it was not taken, because no stop-watch was at hand, and the ordinary pocket-pieces carried by my friends were open to too many sources of error and inaccuracy to be considered available.

THE TRUTH ABOUT "TUBERCULIN."

By JOSEPH WILLIAM STICKLER, M.D.,
ORANGE, N. J.

1. It does not cure pulmonary tuberculosis in either its primary or advanced stage. 2. If administered during the primary stage, it is apt to hasten the progress of the disease. 3. If given during the advanced stage, it is almost certain of hurrying the patient into eternity. 4. It may be given in such small quantities as to produce no appreciable reaction, and yet a very little may, in some individuals, give rise to distressing symptoms. 5. By causing a necrosis of the pulmonary tubercular tissue, it exposes the patient to a risk (septic absorption) which without the tuberculin he does not, to the same extent at least, incur. 6. It is fairly well demonstrated that it liberates the bacilli and favors their migration to distant organs, or to parts of the lungs not originally affected. 7. It creates false hope by producing an apparent temporary improvement. 8. If given for diagnostic purposes, it will probably make the diagnosis clear by giving a fearful, possibly a fatal, momentum to the tubercular lesion, if there be one. 9. It is a poison, and as it has not the power to destroy the bacilli, it is out of place in the animal economy. A tubercular patient has about all the poisons in his system he can tolerate. 10. It is a remedy which thus far has done more harm than good. 11. As it has not the power to cure, or even alleviate, and has the power to make worse or kill, it should not, in cases of pulmonary tuberculosis, be used under any circumstances. 12. If used in surgical tuberculosis, and previously undiscovered tubercular lesions of the lungs be developed by its use, treatment should at once be discontinued. 13. It seems to have the power to arrest the progress of lupus, and in uncomplicated cases may be used without jeopardizing the patient's life. Should latent tuberculosis of the lungs be made manifest by its use in these cases, it should promptly be stopped. 14. As tuberculin is not curative when used alone, and has been demonstrated to be a dangerous agent, it is irrational to use it in conjunction with other remedies in the treatment of pulmonary tuberculosis.

The time has come when the plain truth should be stated, by competent investigators, in relation to the subject under consideration. The results thus far obtained have been discouraging wherever it has been used, no matter how favorable the attending circumstances and conditions as to home, climate, hygiene, etc. I know of none (not one individual) cured. I know of none whose improvement can be clearly traced to the use of tuberculin. You say you know of persons who have been improved by the use of this remedy. If you do, your experience has been at variance with mine. The great majority of observers who have had ample opportunity to test its value, say they have failed of obtaining the gratifying results they had looked for. That it has done great harm in many instances there is not a shadow of a doubt, hence I say it is unjustifiable to continue the use of tuberculin in cases of pulmonary tuberculosis. If it were true that this class of patients had been benefited by it, we might conscientiously employ it, but in view of the fact that such cases cannot be brought forward, the above assertion I consider a safe one to make. So far as surgical tuberculosis, lupus, tubercular glands, and tubercular ulcers of the larynx are concerned, if they be uncomplicated with pulmonary tuberculosis, the remedy may be used with comparative safety. But here again we are confronted by the fact that "cures" are wanting. Let us then be honest and fair in this matter, and say unreservedly just what we believe. I am sure the medical profession received the statement made by Professor Koch in regard to tuberculin with joy and hopeful anticipation as to its future. I am sure the remedy has had a most thorough and searching trial, and such a trial was right and commendable, because the evidence furnished by the early use of tuberculin led us to believe it could arrest the advance of tuberculosis by destroying the tissue in which the bacilli develop and multiply, without compromising the life of the patient. But having made an extensive trial, and having obtained only discouraging results, let us put aside our bottles of "lymph" and look for something which will kill the bacilli. When we shall have found such a remedy or agent we shall indeed have cause to rejoice.

Progress of Medical Science.

Acute Miliary Tuberculosis and Tubercular Meningitis.—Dr. Reinhold recognizes three forms of acute miliary tuberculosis: 1. The typhoid form, with symptoms of a general infection, any local symptoms having retreated into the background. 2. The broncho-pneumonic form, with symptoms chiefly referable to the respiratory organs. 3. The meningeal form, where symptoms referrible to the nervous system predominate. In addition there are transitional forms. Nearly always there is some old tuberculous centre which, owing to its limited extent, or a special localization, cannot be recognized during life; such, for instance, as caseating bronchial or mesenteric glands, obsolescent tubercle in the lungs, etc. Acute tuberculosis may be secondary to bone or joint disease, but rarely to advanced phthisis. At the post-mortem examination after tubercular meningitis tubercle is nearly always found elsewhere. Dr. Reinhold then considers seventy six cases occurring in the Freiburg clinic under the three headings:

1. *Typhoid Form.* — Twelve cases. The diagnosis from enteric fever may be very difficult. Septic diseases, such as ulcerative endocarditis may be mistaken for it. Even rigidity and tenderness in the neck muscles may occur in enteric fever without meningitis being present, and indeed, in cases of miliary tuberculosis without meningitis, these symptoms are rarely met with. Henoch has pointed out how in children with pneumonia, especially of the upper lobes, cerebral symptoms may be present. Irregular temperature with no corresponding change in the symptoms is, in doubtful cases, in favor of tuberculosis. There is no regularity as to the time of the highest temperature in the day. The *typus inversus* is rarely seen. The pulse is faster in tuberculosis, and once fast it usually remains so independently of change in temperature. Irregular pulse is rare except in tubercular meningitis, where it is frequently seen. The value of great frequency of the respiration with hardly any signs in the lungs is important. Increase in the respiration-rate takes place before that of the pulse. The general appearance of the patient in acute tuberculosis is striking—his pallor and great prostration; later slight cyanosis is added to this pallor. As to the eruption, if there are serious doubts as to the disease being enteric fever, not too much stress must be laid upon the appearance of one or two spots, especially if they do not occur at the proper time. Dr. Reinhold then refers to a possible relation between erythema nodosum and tuberculosis, illustrating it by a case, and referring to Uffelmann's experience of the occurrence of this form of erythema in the children of tubercular parents. In tuberculosis the enlargement of the spleen takes place later than in enteric fever, and the tongue has no characteristic appearance. Increasing cyanosis may be the first sign to suggest tuberculosis. The appearance of small

râles here and there in limited patches, and slight alteration in the breath-sounds, especially if this be in the upper parts of the chest, are significant.

2. *Broncho pneumonic Form.*—This may be mistaken for acute bronchitis, but the dry stage lasts longer and the sputum is less in quantity. The primary focus of disease must be sought for, but the proof of this is almost impossible. Truly, bacilli in the blood or tubercle in the choroid can alone be looked upon as absolute proof. Choroidal tubercle is found in about one out of fifty cases upon the disease, although almost without exception the phthisical patients to whom I have given it have thought that they derived great benefit from its use; nor has sufficient time elapsed as I have only [illegible]

3. *Meningeal Form.*—Three kinds may be recognized: (*a*) the very acute form, reminding one of simple meningitis, or even of apoplexy; (*b*) the ordinary more subacute form with especial involvement of the base; (*c*) the markedly chronic form, simulating a psychosis or a tumor. In adults signs of spinal irritation may appear. As to temperature, acute hydrocephalus exercises a depressing effect upon it, as it does also on the pulse. So also does the development of miliary tubercle in the lung, according to the author. There are variations in the temperature even as regards any particular time of day. There may be an ante mortem rise of temperature, but more often there is a decided fall. The rise in temperature is not due to convulsions; it would appear to be brought about by the direct effect of the disease upon the heat regulating apparatus in the brain. Loeb sought to explain it by the amount of the exudation between the chiasma and pons, but it has been found in meningitis limited to the convexity. As to the pulse, there is a slowing—often irregularity—occurring early in the disease. It is subject to rapid changes. In the latter stages of the disease Cheyne-Stokes breathing may be observed. It may appear, then go away, and finally come back again. Those cases of sudden death in this form of meningitis are to be referred to a sudden paralysis of the respiratory centre. Dr. Reinhold says that the tache cérébrale may be of value when extremely well marked. In convex meningitis the pupils are narrowed, in basal unequal and dilated. The amount of intracranial pressure is also of importance. In moderate pressure the pupils are small; in much pressure they are wide. Exophthalmos was noted once. Spasm of the face muscles and paralysis have been referred by Wernicke to cortical trouble, by Strumpell to peripheral disease at the base. As regards motor troubles there may be irritation symptoms, spasm and tremor, or paralysis. These latter may be observed, and at the post-mortem no naked-eye changes found sufficient to account for them. It must, however, be remembered that meningitis is generally combined with a well marked encephalitis, as is proved by the microscope. Sensation may be impaired, and the superficial reflexes, especially the conjunctival reflex, diminished on the weakened side. Prodromal symptoms are most often due to an old local tuberculosis of the brain. A case of Callender's is then referred to, in which there were epileptiform fits for several months before death, and tubercles of the pia were found, but no meningitis. In two cases there was disturbance of speech. Occasionally the mental symptoms are most marked

Spinal Meningitis and its Clinical Symptoms.—Changes are to be found in the spinal cord and in the sensory roots in cases of tubercular meningitis—serous exudation, swelling and disintegration of the axis cylinders, and cell infiltration. Rigidity of the neck is one of the most constant symptoms; it is absent if there be loss of consciousness. Blood in the posterior fossa of the skull may also produce rigidity of the neck. Diffused tenderness over the spinal column is only a part of a general hyperæsthesia. Kernig has described a flexion contraction at the knee-joint as a symptom of spinal meningitis. Hyperæsthesia may apparently exist without the cord being involved. Thus it must not be looked upon under all conditions as characteristic of spinal meningitis. It may be absent altogether in cases where the spinal cord is involved, just as in cerebro-spinal meningitis.—*The Provincial Medical Journal.*

Non-Puerperal Phlegmasia Dolens.—Dr. Cattle states that, under ordinary circumstances, contact with vascular walls which have not lost their vitality effectually prevents coagulation of the blood, and Lister found that blood confined in a vein by means of ligatures remained fluid for hours and even days after removal from the body; while, on the other hand, contact with ordinary inert solids hastens coagulation (*The Provincial Medical Journal*). This restraining influence of the living vessels is supposed by Cohnheim to reside in their endothelial lining, in virtue of which the coagulating tendency of small quantities of fibrin-ferment is rendered inoperative. From this it would follow that two sets of causes may operate in bringing about thrombosis: those which by injuring the endothelium destroy its functions; and those which, by increasing the amount of free ferment in the blood, increase its tendency to coagulate. According to Cohnheim, sluggishness and even stagnation of the blood do not in themselves occasion intravascular clotting, but in virtue of the impaired nutrition of the endothelium consequent upon the blood-stasis. In this condition clotting is apt to commence in the pockets of the venous valves, and from these points of origin may extend until considerable thrombi are formed. Free fibrin-ferment is formed during disintegration of white blood-corpuscles, and in lesser degree, of red corpuscles. In connection with jaundice it is interesting to note that the presence of the salts of the bile-acids in the blood causes solution of the red blood-corpuscles, with liberation of free hæmoglobin and fibrin-ferment. Under such conditions it is possible to produce acute thrombosis, at any rate experimentally; but Cohnheim does not consider the presence of cholates in the blood, occurring in the course of disease, a frequent cause of thrombosis. The part played by the white corpuscles in coagulation has been beautifully shown in experiments for the artificial production of thrombi, and which afford a clue to the mode of formation of white thrombi during life. When the process of thrombosis is observed under the microscope, the white corpuscles are seen to adhere in successive layers to the sides of the vessel, gradually becoming more densely packed together. Afterward the corpuscles degenerate, losing their nuclei and cell boundaries, and finally are converted into a granular amorphous substance indistinguishable from fibrin, but in the meshes of which large numbers of well-preserved white corpuscles still exist. Greater familiarity with the properties of the various proteids contained in blood has led to modification of the original views of A. Schmidt on fibrinogenesis by Hammarsten and others, who have shown that there exists only one antecedent of fibrin in blood plasma—viz., fibrinogen, and from it fibrin originates, in presence of the ferment. This latter according to Halliburton, is also a proteid of the globulin class derived from the disintegration of the white blood-corpuscles (hence the term "cell-globulin"), and probably of the blood-tablets also (Osler). Had Dr. Wooldridge lived to continue his investigations on the phenomena of coagulation, he would probably have added materially to our knowledge both of its physiology and pathology; but up to the present time his views as to the greater importance of lecithin, a phosphorized fat, than of the fibrin-ferment in initiating coagulation, have received no very wide acceptance or confirmation. As the essential causes of clotting, whether in the vessels or outside them, cannot differ very widely, it may not be altogether out of place for practitioners of medicine to seek for light, from physiological researches, and by so doing hope for insight into obscure pathological problems.

Precautions Against Yellow Fever.—Hereafter all vessels coming to this port from yellow-fever infected places are to be examined off the quarantine ship in the lower bay.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

SURGICAL TREATMENT OF TUBERCULOSIS BY CHLORIDE OF ZINC.

PROFESSOR LANNELONGUE, of Paris, has recently made a communication to the Académie des Sciences and the Académie de Médecine, which is regarded, in France at least, as of the very highest importance. The communication purports to describe a new method of treating tuberculosis, more especially of joints. This method is a surgical one and consists, so far as we can learn, of injections into the affected parts of chloride of zinc, the object being to produce a sclerosis of the parts peripheral to the disease.

Experiments, says Lannelongue (*The Lancet*), have shown that chloride of zinc produces a remarkable fibroid change in the normal tissues of animals, and, as might be expected, the same fibroid transformation is brought about by the same agent in morbid tissues in general, including the tubercular. This chemical compound may be said to fix the anatomical elements by killing them, for it obliterates the capillaries and smaller vessels around where it has been deposited. An inflammatory action is thus set up in the vascular walls, which narrows the calibre of the surrounding vessels for a considerable distance from the initial point. But over and above this another local change of the highest import is brought about. Very rapidly—even within a few hours—there is produced in the altered tissues, by transmigration, and probably also by cell proliferation, an enormous afflux of new anatomical elements. These young cells cause fresh œdema of the periphery of the granulation growths, and infiltrate the tubercular neoplasm to the fullest extent. From this moment the struggle sets in between the accumulated elements and the bacilli, especially between the migratory cells and the microbes, to the detriment of the latter. However it may be as to the strife between cell and bacillus, the elements of the morbid growth which the chloride of zinc had destroyed are reabsorbed slowly, and finally disappear. The young cells, on the contrary, organize with great activity, and form a firm fibrous tissue, which is met with in appreciable quantity as early as the day next after the injection.

Following the sclerosis in articular fungosities, there is produced a thickening and subsequent condensation of osseous tissue if the periosteum be involved in the reparative process, as was the case in the examples of osteo-arthritic disease cited by the author. The remote results, so far as it is yet possible to judge, show a marked tendency for the sclerosed elements to be replaced by a more pliable connective tissue. As a consequence, the diseased parts regain their suppleness and their form, while locomotor functions are preserved entirely, or at least to the limits present at the beginning of the treatment.

Dr. Lannelongue has been at work for two months on [illegible] furnished by the early use of tuberculin led us to [illegible] it could arrest the advance of tuberculosis by destroying the tissue in which the bacilli develop and multiply, without compromising the life of the patient. But having obtained only [illegible] and having obtained only dis-

Our exchanges do not yet furnish details of the technique of the method, which does not seem to us a particularly novel or rational one.

A PROPOSED MONUMENT TO AVICENNA.

AVICENNA, "the Prince of Physicians," died some nine centuries ago, aged fifty-eight years. It is now proposed, by the Berlin physicians, to erect a monument over his neglected grave. The proposition is most creditable to the historic sense of the profession, and we hope that the learned gentlemen of Berlin who are initiating the movement will be successful in it.

Avicenna, M.D., was born about 1000 A.D., "in that delightful province of the Sun," Khorassin, and he lived an interesting and variegated life. The doctor was a good deal of a politician, but he did not have a steady "pull" with the authorities. He got himself appointed grand vizier, but was shortly deposed, imprisoned, then reinstated, and finally deposed again and banished the country. He was a gentleman, evidently, of great but erratic talents, and is reported to have looked too much on the wine when it was red in the cup. He wrote a very good treatise on practical medicine, called the "Canon," which was used as a text-book by medical students for several hundred years, and which must have run through a good many editions.

Dr. Avicenna was a brilliant man beyond any doubt, and ought to have a monument. But so, perhaps, ought Rhases, Averrhoes, Albucasis, Avenzoar, and especially Honain, who, for true moral worth, perhaps exceeded them all. If, therefore, we undertake to honor the memory of the Arabs, it might be wiser to have a conjoint tablet and put on all the names. As soon as our American brethren have finished their monument to Dr. Rush, we trust they will take up the Arabs.

OPIUM SMOKING IN PHTHISIS.

DR. JOHN GORDON DILL, in *The Lancet* of July 11th, makes the rather dangerous statement that opium smoking, when done in a certain way, affords great relief to phthisical patients. "My custom," he says, "has been to soak the tobacco in Battley's liquor opii sedativus, choosing this preparation because it contains all the component parts of opium in a fluid form, and to use it when it has dried. I have given this mixture in various proportions, and I think that a useful strength is three fluid drachms of the Battley to one ounce of tobacco; but of course it can be made much stronger than this. I usually advise the patient not to smoke just before eating, and I never in any case tell him how the tobacco is medicated. The most

marked therapeutic effects of smoking opium in this way are that it eases the cough, and acts as an expectorant, "cuts the phlegm," as the patient often expresses it. One poor man assured me that he had not the strength to get up in the morning until he had smoked part of a pipe to relieve his chest. The material which I have collected is not yet sufficiently large to draw any conclusion as to whether opium administered in this form has any specific effect upon the disease, although almost without exception the phthisical patients to whom I have given it have thought that they derived great benefit from its use; nor has sufficient time elapsed, as I have only employed it for two years, to make sure that the improvement which has taken place in any case is permanent. In this connection two sources of error in considering the effects of any treatment upon the course of pulmonary tuberculosis have, I think, been quite left out of sight in the numerous statistics which have recently been published. The first is the fact that tuberculosis is an undoubtedly curable disease in certain cases, and it is quite possible to conceive that a coincidence of the cure and of the particular treatment adopted may explain many excellent results."

Dr. Dill adds suitable words of caution in regard to the dangers which the practice recommended involves, but he is inclined to think that these dangers have been exaggerated.

We are not told whether or not his patients inhale the smoke, but infer that they do not. The point is a very important one in the technique.

MR. BLAINE AND THE MANAGEMENT OF MENTAL DEPRESSION.

Dr. J. M. Taylor has just contributed to the *University Medical Magazine* an article entitled "Hints on the Management of Mental Depression." The article is a suggestive one in connection with the present reports regarding the condition of Dr. Taylor's patient, Mr. Blaine, and we cannot but think that he had that distinguished gentleman much in mind while writing.

We suspect that something of his case is embraced in the following account of "young Mr. B——," of whom, after some preliminary history of excessive devotion to social duties, Dr. Taylor says: "The other factors in this young man's case might be said, in brief, to be an inherited tendency to gout, which showed itself in excessive uric acid, and in acid dyspepsia. There was also, probably as a result of all these things, an increasing sleeplessness, a worried sense of responsibility which led him to feel that he was getting behind in his daily routine and unable to keep up; finally, an exaggerated notion that he might, at any moment, be ill and unable to fulfil his engagements, and the also exaggerated conscientiousness that if he should so fail others would suffer for his neglect. Finally, on two or three occasions a feeling of faintness came on in the street or elsewhere, naturally suspected to be cardiac, and presently there was established a wretched, nervous fear lest he might break down at any moment of some great responsibility and disgrace himself. This went on until he was practically unfit to even attempt the continuance of his old life. Then came the extreme mortification of confessing himself beaten. This superadded chagrin to incapacity, and all was colored by a Spartan desire not to let it be known how he felt. Then I assure you that this young man's condition was most pitiable."

The writer proposes to give some hints on the treatment of hypochondriasis and mental depression, but as a matter-of-fact, he simply shows us that such cases have to be managed rather than treated. The patient needs a person of tact, intelligence, and energy; and one who is not a personal friend or at least an intimate. All these facts are very well known and have often been dilated upon, but Dr. Taylor presents the story anew in an interesting manner.

PRE-COLUMBIAN SYPHILIS.

The growing prospect of a world's fair in 1892 or 1893 arouses an especial interest in things Columbian and pre Columbian. Possibly among the latter may be classed syphilis. Dr. James Nevins Hyde discusses the question in the *American Journal of Medical Sciences*, and the discussion will, we trust, be continued. America has heretofore accepted too readily the dubious compliment of having bestowed upon civilization the *grosse vérole*. When one recalls what a sty of licentiousness and filth Europe was in the fifteenth century, it seems much easier to suppose that syphilis was bred there than that it was imported. Dr. Hyde, however, takes up mainly the question whether the North American Indians of pre-Columbian times left any bones which show evident syphilitic lesions. A good many so-called pre historic bones showing signs of so called syphilis have been collected. But it has been shown that many of the remains in the Indians' mounds and caves are not pre-historic. Then, so far as the lesions are concerned, it appears to us from the evidence presented that none of them are plainly the results of syphilis. Dr. Hyde reports in detail the results of a microscopical study of two tibiæ from Colorado, made by Dr T. M. Prudden. These showed the presence of a chronic rarefying and formative osteitis and chronic formative periostitis, changes which might be of syphilitic origin, but much more likely were not.

So far as the bones have yet told the story there was no pre-Columbian syphilis.

Its presence will have to be established by further bony studies, as well as by historical, and perhaps philological investigations.

AN INTERESTING HOSPITAL.

For a restful piece of literature we refer our readers to pages 5 and 6 of the Report of the Cook County Hospital, situated in an area annexed to the town of Chicago, Ill. We bespeak special attention to page 5, containing a tabular arrangement of the Medical Boards, of which there are three, viz., the regular, the homœopathic, and the eclectic, all of these being not only full but bulging. Such a happy combination of elements once thought discordant is an object lesson in harmony which the profession may do well to study. One can only regret, in the interests of an even truer catholicity, that the Electro-vitapathists and the Bichloride of Gold Club have not also some representation.

The numerical richness of the medical boards also impresses one as showing a generosity of spirit and an in-

dulgence toward hyperplasia, on the part of the Cook County authorities, not found in less enlightened communities. When it comes to variety and quantity of medical boards, its hospital is going to lead the van of progress untrammelled by hackneyed precedents or the trivial consideration of actual necessity. Thus statistics show that Cook County Hospital admits 375 gynecological cases in one year, for which it provides 7 regular, 1 eclectic, and 2 homœopathic gynecologists. This gives 37½ cases per year, to each visiting professor. Besides this the hospital has 15 surgeons, 13 physicians, and enough oculists, dermatologists, etc., to bring up the total to 47.

For a hospital of five hundred beds this is a thoughtful allowance. We are pleased to note also the names of Mary and Alice among the members of the three kinds of house-staff. Cook County evidently makes no distinction of sex or sect, and seems, indeed, to be a pleasant and instructive type of the liberality and greatness of our modern municipal institutions.

PARANOIA AND THE MILLENNIUM.

A BELIEF that the world is coming to an end within a few years is not evidence of insanity. A good many persons of credulous temperament, limited knowledge, and weak judgment have entertained such beliefs and yet were sane and useful members of society. When such a view, however, is held and advocated by a professor in a great university, who has presumably received a sound and liberal education, and has particularly qualified himself in the exact sciences, the fact is suspicious. When, further, such a man promulgates his views with intense ardor and accompanies his preaching with diagrams and elaborate mathematical tables which a close examination shows are utterly unmeaning and nonsensical, suspicions of insanity ripen to certainty.

Our esteemed contemporary, *Frank Leslie's Illustrated Weekly*, prints and illustrates the views of such a learned and erratic professor in much detail. They are worth studying as most typical and beautiful illustrations of the workings of the paranoiac brain. Similar pictures, tables, and weak attempts at reasoning are seen in every asylum. They illustrate the development of the systematized delusion of which the person in question is a victim.

We do not call attention to the facts thus mentioned because of their scientific interest alone, however. But it so happens that such teachings, issuing as they do from a person who holds a high position as a teacher, may do harm by exciting and disturbing the minds of the uncritical and setting off into a similar mental aberration persons who are ripe for such a disaster.

THE PATHOLOGICAL ANATOMY OF ADDISON'S DISEASE.

THE pathology of Addison's disease has never been very satisfactorily made out. It has been admitted that the supra-renal capsules are generally diseased, but the uniform existence of this is denied; while, on the other hand, the capsules have been found diseased in persons who never had the bronzed skin. Furthermore, even supposing that these organs were uniformly affected, it has been difficult to understand how au affection of such apparently insignificant bodies should give rise to a malignant and progressive constitutional disorder.

A few years ago we called attention to some researches which apparently cleared up this latter point. It was shown that the bodies in question were blood-glands and had the function of selecting from the blood and destroying certain poisonous pigmentary products of metabolism. This function being destroyed, the poison circulated in the system and was deposited in the skin and mucous membranes. The process was similar to that of the thyroid gland, whose destruction led to the deposit of myxomatous tissue and myxœdema.

In the *Revue de Médicine*, for April, 1891, Drs. Alezais and Arnand have gone over the subject of the pathology of Addison's disease again.

They have reviewed the literature and tabulated the post-mortem records in forty-nine cases, including four of their own.

They reach the conclusion that Addison's disease is accompanied almost, if not always, with a pathological alteration of the supra-renal capsules. In the great majority of these cases this alteration is of a tuberculous nature.

A lesion of the parenchyma of the gland itself cannot cause the general disease. It is only when the process has extended further and involved the nerves and cells supplying the capsule (peri-capsular ganglia) that serious symptoms supervene. The lesion may even be limited to these nervous structures, the gland itself not being involved, yet the bronzed skin will develop. This latter fact explains the alleged absence of supra-renal disease reported in some autopsies.

News of the Week.

The American Electro-therapeutic Association will hold its first annual meeting at the hall of the College of Physicians, corner of Locust and Thirteenth Streets, Philadelphia, Pa., on Thursday, Friday, and Saturday, September 24, 25, and 26, 1891, under the presidency of Dr. G. Betton Massey. Physicians interested in the discussion of electricity in medicine are invited to attend without further notice.

HORATIO R. BIGELOW, M.D.,
Chairman Executive Council,
WILLIAM H. WALLING, M.D.,
Secretary,
2005 Arch Street, Philadelphia.

Nocturnal Enuresis.—A correspondent of the *Lancet* advises for this trouble that the old-fashioned remedy of a birch-rod be employed shortly before the boy is put to bed; six not severe strokes, repeated for two or three nights at the outside, will effect a cure. The birching should be regarded by all parties not as punishment for the past, but as treatment for the future—a very different thing. The *rationale*, he thinks, is, 1, that it wakes up a desire to avoid wetting the bed; 2, that it draws the blood to the surface for a few hours, and thus relieves the pelvic organs; 3, that it stimulates the lumbar centre, controlling micturition through the nerves distributed to the upper gluteal region; and 4, that it prevents the patient lying on his back.

Medical Congress in Cuba.—A medical congress will be held in Cuba in 1892. The following subjects will be presented for discussion: "Topography and Medical Statistics in Some One Locality in the Island of Cuba;" "Etiology, Prophylaxis, and Treatment of Yellow Fever;" "Pathology of the Liver in Hot Climates;" "Is Malaria the Cause of the Malignity of Fevers in Havana?" "Scheme for the Improvement of the Sanitary Condition of Havana."

A Memorial to Matthews Duncan.—It has been proposed, by the friends and pupils of the late Matthews Duncan, to perpetuate the memory of the great obstetrician by founding at St. Bartholomew's Hospital a Matthews Duncan medal or prize in obstetrics or gynecology, and the erection of a bust, to cost from $6,000 to $7,000.

A Worthy Institution.—An announcement appears in a Montana paper that Dr. H. F. Musser has recently opened a hospital, where the unfortunate rich can find excellent treatment and comfortable quarters.

Medical Law in Nebraska.—A law which goes into effect next month provides for a State Board of Health, to consist of the Governor, Attorney-General, and Superintendent of Public Instruction, who shall appoint four secretaries, who shall be graduated physicians of at least seven years' practice. It is made unlawful for any person to practise medicine, surgery, or obstetrics, or any of the branches thereof, in the State, without first having obtained and registered the certificate provided for by the act; and no person shall be entitled to the certificate provided for unless he shall be a graduate of a legally-chartered medical school or college in good standing; said qualifications to be determined by the board. The penalty for infringement of the law is a fine of not less than fifty nor more than three hundred dollars.

A Bust of Hebra was unveiled on June 14th in the arcade of the University in Vienna. An address was delivered by Professor Kaposi.

The American Public Health Association, constituted of representatives of the United States of America, the Dominion of Canada, and the Republic of Mexico, will hold its nineteenth annual meeting at Kansas City, Mo., October 20, 21, 22, 23, 1891. The following subjects will be considered: 1. "Sanitary Construction in House Architecture; *a*, Heating; *b*, Lighting; *c*, Drainage; *d*, Ventilation." 2. "Railroad Sanitation." 3. "Meat-supplies." 4. "Milk-supplies of Cities." 5. "Arsenical Papers and Fabries." 6. "Isolation Hospitals for Infectious Diseases in Cities." 7. Papers upon any of the subjects upon which special committees have been appointed. 8. Papers on miscellaneous sanitary and hygienic subjects.

The Inspection of Hog Products at the Stock Yards is in operation, and in a short time every hog killed in Chicago will, it is hoped, bear the government stamp attesting its freedom from trichinæ. At present thirty microscopists are employed, and a piece of the diaphragm is the part usually selected. Already many hogs have been condemned, though only a small portion of the daily output is submitted to such examination. The moral is obvious.

Cook County Hospital.—The County Commissioners have appropriated eighty thousand dollars for two new pavilions at the Cook County Hospital, thirty-five thousand dollars for a morgue, forty thousand dollars for a detention hospital for the insane, and forty thousand dollars for detached wards for contagious diseases. Plans are perfected, and building will go rapidly on, that for the detention hospital and morgue being well under way.

The Oakland Medical Club, of Chicago, is a new organization of physicians with a strong social bias and a purpose to inculcate the best friendly relations among its members. They meet once each month at table and indulge in a mildly professional discussion. The "Sunset Club" has been imitated in a declaration of principles. The requirements for membership, from the following official statement, may appear a trifle broad. Object: The Oakland Medical Club is to foster rational good fellowship and tolerant discussion among physicians. Requirements for membership: Any genial and tolerant physician may become a member on approval of the Executive Committee. Programme: A dinner the last Friday of every month, at eight o'clock, followed by short talks upon a topic previously announced by the Secretary. Expenses: The only expenses incident to membership in the Oakland Medical Club are an annual assessment of one dollar for stationery, printing, etc., and the price of each dinner partaken of. Guests: Members are privileged to bring guests to the meetings, provided notice is sent to the Secretary in time to prepare for their entertainment. The experiment will be watched with interest.

Professor Koch Resigns.—It is stated that Koch has resigned all his official positions. This, we are told, is not on account of the failure of his tuberculin, but because he is upon the point of accepting a new office, that of Director of the Institute of Infectious Diseases, which has been organized by the German Government. It is also stated that the Academic Senate will bestow an honorary office upon Professor Koch, and that this will permit him to lecture whenever and wherever he pleases.

The University of Vermont.—Dr. Condict W. Cutler, of New York, has been appointed Professor of Skin and Venereal Diseases, to succeed Dr. R. W. Taylor, who has resigned.

Charge Against Professor Bergmann and Dr. Hahn.—It is stated that Professor Bergmann and Dr. Hahn have been ordered to answer within twenty-four hours the charges of having inoculated pauper patients with cancerous matter.

The Progress of Cholera.—Cholera is still spreading in Abyssinia, the disease making great progress at Massowah, where not only natives but some Europeans have been attacked. The heat is stated to be excessive. It is also alleged that some cases have occurred among pilgrims at Mecca, and that detention at Red Sea ports is already being arranged for pilgrims before returning to Egypt or passing up the Suez Canal. The occurrence of the disease at Aleppo has led to quarantine being imposed by the Austrian Government on all arrivals from Syrian ports between Karatash and Latakia, and the same regulation will apply to arrivals from Red Sea ports.

Donation to a Hospital.—The Ospedale Maggiore at Milan has just received from the Duchessa Eugenia Litta Bolognini, who recently lost her husband and her second son, a donation of 500,000 francs—the proceeds of the sale of her jewels. The special department of the hospital thus munificently endowed is that of the Children's "Clinico-Chirurgico," or ward for the surgical lesions of children, and is intended as a memorial to the young Duca Litta Bolognini, prematurely deceased.

International Congress of the Red Cross.—The Red Cross Associations organized in the European States which have signed the Geneva Convention have had the laudable custom of holding international meetings, at which the interests of the sick and wounded in war are practically considered, and the arrangements for a more effective and harmonious furtherance of those interests discussed and agreed upon. The first of these congresses was held in Paris in 1867, the second at Berlin in 1869, the third (*longo intervallo*) at Geneva in 1884, and the fourth at Carlsruhe in 1887. At this latter it was resolved that in future the congresses should meet every five years, the *locus in quo* of the succeeding congress being then undecided. The International Committee of Geneva has just proposed that the congress should hold its fifth meeting in Italy next year, and the Central Italian Committee, duly notified of the fact, has completed negotiations with the Government, according to which the seat of congress will be Rome, and April or May, 1892, the month in which it will assemble.—*Lancet.*

The "Ripper" Case.—In a recent issue of *The New York Medical Journal*, Dr. Austin Flint describes the questions with which the medical experts were confronted and the grounds on which they swore that various blood-stains contained intestinal matter from the same person. These grounds were chiefly that all the stains contained bilirubin and tyrosin, substances which, it is asserted, would not appear in the large intestine.

Growth of Interest in Hygiene.—The growing interest of the public in hygiene is shown by the recent report of the Secretary of the Maine Board of Health. A dozen years ago local boards of health were almost unknown in the State; now there are reports from four hundred such boards out of a total of four hundred and thirty towns. As a result of this hygienic organization, outbreaks of diphtheria, scarlet fever, and typhoid fever have, in almost all instances, been confined to the primary cases or the first family the past year; while one hundred and twenty local reports expressly state that no cases of any one of these diseases occurred during the twelve-month, and forty others fail to mention any such cases.

Patent Medicines in the United States.—In an address, recently delivered by Dr. John S. Billings, "On American Inventions and Discoveries in Medicine, Surgery, and Practical Sanitation," he stated that between the years 1880 and 1890 the number of patents granted for medicines in the United States was 540. According to the census of 1880 there were in the States 592 establishments devoted to the manufacture of drugs and chemicals, the capital invested being $28,598,458, and the annual value of the product $38,173,658. In addition to these there were 563 establishments devoted to the manufacture of patent medicines and compounds, the capital invested being $10,620,880, and the annual value of the product $14,682,494. Dr. Billings went on to say: "We are a bitters and pill-taking people. From the commercial and industrial point of view, the great importance of patent and proprietary medicines is connected with advertising The problem is to induce people to pay twenty-five cents for the liver-encouraging, silent-perambulating, family pills, which cost three cents." America is as pre-eminent in the number of its dyspeptics as it is in the number and variety of its medical degrees, and the philosophic mind might not unprofitably exercise itself in solving the problem whether the national indigestion is the cause of the pill-taking, or the pill-taking is the cause of the indigestion.

Post-Graduate Institutions Seem to be Getting Ahead.—Dr. W. S. Christopher has resigned the chair of Theory and Practice of Medicine in the University of Michigan to take the chair of Diseases of Children in the Chicago Polyclinic.

The Health Officer of Washington.—Quite a contest has been going on in Washington, D. C., over the position of Health Officer of the District. Dr. Smith Townsend, who has discharged the duties of this office for some years with eminent satisfaction to many people in the District, has been requested by the Commissioners to present his resignation. This Dr. Townsend refused to do. The Commissioners have therefore removed Dr Townsend from said office and have appointed to this position Dr. C. W. R. Hammett, a well-known physician of that city. The cause of Dr. Townsend's removal has not been stated, but it is intimated that his removal was made out of deference to political considerations.—*Maryland Medical Journal.*

Army and Navy Medical Candidates.—During the past ten years 384 candidates have presented themselves to the Army Boards, of whom 76, or 22.3 per cent., passed, and 31 were rejected for physical disqualifications, and the remainder failed to pass the medical examination. During the same period, 237 candidates presented themselves before the Navy Board, of whom 55 were approved and passed, 75 rejected for physical disqualification, and the remainder either withdrew or failed to pass.

The British Medical Association in Canada.—Mr. Ernest Hart, the editor of the *British Medical Journal*, has recently made an extended visit to Canada, and during his stay there has established three new branches of the British Medical Association, one in Toronto, one in Montreal, and one in Winnipeg. The association has now 13,500 members, of which number 2,000 reside in other parts of the Empire than Great Britain. It has a reserve fund of over $200,000. Its Colonial membership is said to be largely increasing.

Dr. W. H. Taylor, one of the most prominent young physicians in New Bedford, Mass., and medical examiner for that district, died on July 20th. He was a son of James Taylor, Collector of the Port.

Leidy Chair of Anatomy.—It has been decided to raise a fund for the endowment of a Leidy Chair of Anatomy in the University of Pennsylvania. It is proposed also to establish and endow a Leidy Memorial Museum.

Society Reports.

ONTARIO MEDICAL ASSOCIATION.

Eleventh Annual Meeting, held at Toronto, July 3 and 4, 1891.

W. H. MOOREHOUSE, M.D., PRESIDENT, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

AFTER presentation of the reports of the preliminary committees the regular work of the session commenced with

Carcinoma, by DR. TESKEY, of Toronto, who delivered the Address on Surgery, taking for his subject the etiology and treatment of cancer. He briefly referred to the two theories as to the cause of cancer: 1, Considering it to be an abnormal growth of epithelium, the result of the action of an irritant; 2, that it is due to a special microbe. In the development of carcinoma, irritation, he believed, played an important part, and in many instances inflammatory products, at first simple in character, by prolonged irritation took on a malignant form, the lymphatic glands were gradually involved, and the tumor ultimately became a malignant one. He believed it quite possible for the changed character which the epithelial cells possess to be induced by simple irritation, and cited examinations of doubtful growths wherein many cells possessed malignant characters, while others were perfectly normal. He spoke of the tendency in some cases to natural cure by sloughing, and cited a case of cancer of the breast where a suppurative process appeared to arrest the growth and development of a tumor which to all appearances was cancerous. He had had the same under observation for seven years, and so far there was no evidence of a return of the malignant action which at first characterized the growth. As to the method of dealing with cancer by operation, one would conclude that if an abrasion, fissure, or ulcer resists treatment and will not heal after reasonable time, say two months, free excision should be performed. If we have a cancerous tumor definitely localized, we should remove it and cut wide of the disease. In cases in which the glands are involved secondarily, it seems useless to attempt operation; the hemorrhage occurring during the operation lessens the resisting powers of the patient, the disease progresses still more rapidly, and a fatal termination is hastened.

DR. WISHART, of London, considered the cancerous process clearly allied to chronic inflammation, with the difference, however, that while inflammation exhibited a tendency to recover, in cancer there was a tendency to secondary growths and a progressive increase in the size of the tumor, which was not affected by palliative treatment. He regarded local injury as a cause of many cases of cancer. In regard to the theory of "high living" being a cause of the disease, he said that it was noteworthy that in Africa, where the inhabitants live on simple food and take regular exercise, there is little or no cancer. If the disease were hereditary the whole human race would probably be affected by this time. In regard to the operation for removal, he emphasized the importance of removing every portion of the diseased tissue.

DR. GROVES, of Fergus, thought that while heredity must not be looked upon as a cause, yet there is apparently transmitted in some families a weakness in the resisting power of the individual. Irritation alone is not sufficient. He thought pigmentation and similar changes in cell-elements might operate as a predisposing cause.

DR. SENN, of Chicago, said that it was a disgrace to modern surgery that we know little more about this subject than we did twenty years ago. All evidence was, he considered, against the theory of irritation or local injury being a cause sufficient to produce carcinoma. He dwelt upon the theory of Cohnheim that embryonic elements remaining among the tissues accounted for the origin of cancer. No degree of irritation will cause carcinoma if the necessary condition of the cells be absent. The individual must be born with these embryonal cells, and although he might go through life without developing cancer, it was because the exciting cause had not presented itself. In treatment he advocated early and thorough operation. No credence must be given to the idea that cancer tends to a spontaneous cure, the investigations of Virchow and others having clearly refuted such theories.

Bone-grafting.—DR. W. OLDWRIGHT, of Toronto, presented a patient illustrating treatment by Senn's decalcified bone-filling. While the treatment had not been a complete success in that the wound did not heal by the first intention, the progress of the case furnished an opportunity of observing the process of granulation tissue growing into and incorporating itself with the decalcified bone. The patient, aged nineteen, a cattle drover, had slipped and injured his leg. There was no evidence of fracture, but a marked hardness over the tibia which continued for eight months, when an operation was performed for the removal of dead bone. A considerable quantity was removed, leaving a large cavity. This was carefully treated with a twelve per cent. solution of chloride of zinc, followed by bichloride of mercury, 1 to 500. The bone chips were cut into strips and packed into the cavity after first being dusted with iodoform. The bone chips used were from the tibia of an ox, and were cut in pieces two inches long and then placed in hydrochloric acid to decalcify. The acid was removed by washing in caustic potash, and subsequently the chips were preserved in 1 to 500 solution of bichloride of mercury in alcohol. Before using the chips they were washed in a weaker solution of bichloride and then powdered with iodoform. He considered that while the wound in the case presented did not heal by first intention, the process of reproduction of new bone in the cavity was much facilitated.

DR. SENN said that he thought the partial failure in this instance was either due to the bone cavity not being rendered thoroughly aseptic, or more probably, the parts were in such a diseased condition that reparative processes were slow to occur. The bone chips were not intended to replace bone directly, but merely to act as a temporary absorbable tampon. He urged the importance of making the operation thorough, using the chisel, never the trephine, freely until the whole cavity is exposed and carefully scraped. Next disinfect the cavity with chloride of zinc solution, or better, because it permeates more deeply, the peroxide of hydrogen. Then irrigate with perchloride of mercury and dust with iodoform. After packing in the chips, which have previously been rendered thoroughly aseptic, the periosteum must be stitched over, and if an antiseptic condition has been secured granulation-tissue will gradually be substituted for the chips. Many make a mistake in believing that the chips are used for the permanent replacement of the new bone, but this is not so; they are replaced by granulation tissue in the first place, an early definite healing takes place, and eventually regeneration of the entire bone is brought about.

The afternoon session was opened by Dr. W. H. MOOREHOUSE, of London, in the

President's Address.—After giving a *résumé* of the history of medicine from the time of Hippocrates to the present time, touching briefly the salient features of the different epochs, he dwelt on the advantageous position of medicine at the present day, and referred to the high standard of medical education in Canada. The progress made in promoting the establishment of the Ontario Medical Library was alluded to, and the growth of the library was such that the members of the profession throughout the Province might well be proud of the success of the efforts made to provide such a literary storehouse, to which each member of the profession might resort or apply for books of the highest value for reference in every department of

medical science. The question of club practice was touched upon in terms of condemnation, and the strongest disapproval was expressed against this species of practice, so derogatory to the profession. He considered that any member of the Association who persisted in this baneful practice should be held accountable for such conduct. He deprecated in strongest terms the habit of a few practitioners who consider it proper to advertise their specialties in the public press. This was in direct violation of the Code of Medical Ethics, and must be discouraged. In conclusion he expressed the pleasure it was to welcome such a number of American delegates, whom he greeted in the most cordial terms.

Intestinal Anastomosis.—Dr. N. Senn, of Chicago, was introduced and read a paper on this subject in which he gave a demonstration of his method of operating.

The Cardiac Phenomena of Rheumatism.—Dr. A. McPhedran, of Toronto, opened the discussion on medicine. He prefaced his remarks by claiming that the heart affections are actually an essential part of the disease, and must be considered in association with the other and more usually manifested phenomena of rheumatism. The cardiac complication might appear alone as in the case of children, or it might be combined with other symptoms. Generally in the adult there was a connection between the severity of the symptoms and the frequency of the heart affection. The younger the subject, the more liable was the cardiac complication to be manifest. In children one to ten years of age, eighty-three per cent. have heart lesions; from ten to twenty years, sixty-nine per cent.; from twenty to thirty years, fifty-one per cent.; from thirty to forty years, thirty per cent., and from forty to fifty years, twenty-one per cent. From these figures it was shown that in early life rheumatism nearly always attacks the heart. Many reasons have been given to explain why the heart was chosen as the point of attack. Anæmia was given as one of the causes, and was supported by the frequent examples of rheumatism occurring in young females, so often subject to anæmia. Endocarditis is the most common form, and the mitral valve is most often involved. In children the cardiac phenomena, at first mild, soon return and prove fatal, the lesion increasing with each attack. The inflammatory process is circumscribed in the endocardium because of its want of vascularity. The mitral valve is most affected because its central parts have a good blood-supply. The aortic valve has not such a good vascular supply, and is therefore more apt to escape. The cardiac murmur, according to Sibson, is not the sign of a commencing endocarditis, but occurs when the inflammation is passing off. The first sign of mitral obstruction is a seeming reduplication of the first sound, heard only at the apex; of mitral incompetence, prolongation of first sound heard at the apex. Murmurs occur earlier in rheumatism than in such diseases as typhoid. Pericarditis and myocarditis are often overlooked and misinterpreted; they occur most often in first attacks, severe attacks, and between the ages of fifteen and twenty-five years. Severe and fatal cases may occur without any symptoms. The immediate prognosis of the cardiac lesion is favorable, because in young children, in whom the lesion is most apt to occur, compensation is more quickly established and is more complete, therefore it is but seldom that cyanosis or dropsy occurs. In older patients the prognosis depends on the extent of the sclerotic and atheromatous changes. In the well-to-do, the prognosis is better, because they are subject to less exposure and to less violent exertion. As regards treatment, while we cannot prevent rheumatism, we can save the heart in many cases by arresting the rheumatic process with alkalies or the salicylates, by promoting exertion to purify the blood, by good nourishment in the form of light liquid food, and by rest, particularly in children. Great caution must be taken in the use of alkalies in anæmic cases, for they, by increasing the anæmia, may cause the cardiac lesion. In such cases iron is of greatest value.

Dr. Macullum, of London, said that the endocardium was subject to the same sclerotic changes as the aorta; these were seen chiefly at the valves, but might exist on any part of the endocardium. The myocardium might also be affected, but it is impossible to express an opinion as to its condition save after microscopical examination. The dilatation of the heart was due, not to want of contractility, but of elasticity. Rheumatic patients should have special attention paid to the heart, owing to the round-cell infiltration and vascularization of the endocardium. He believed that for a year after convalescence the patient should be put on a course of alkalies, iodide of potash, and iron, the iodide of potash given for the same reason as in aneurism.

Dr. Charles Sheard, of Toronto, did not think that second attacks of rheumatism were more likely than primary ones to produce cardiac lesions. A slight swelling, a tumefaction as it were, of the valves, he considered the real cause of the first appearance of the cardiac murmur. Each recurring attack increased the deposition on the valves. The heart was best treated by rest. Iron is useless in the anæmia of endocarditis, unless the patient was enjoying perfect rest. He believed this to be true of the use of iron in all cases of anæmia, due to any cause whatsoever. Time and again he had seen this in anæmic girls. He gave his preference to salicylates, but would use alkalies for twelve months after the attack.

Dr. McPhedran, in closing this interesting discussion, first disputed the usefulness of iodide of potash in the cardiac diseases of rheumatism, on account of its tendency to produce anæmia. He did not think the tumefaction referred to was sufficient cause for the murmur. His experience, substantiated by post-mortem evidence, was that pericarditis, though often overlooked in diagnosis, occurred more generally than was thought to be the case.

Alcohol in Medical Practice.—Dr. Arnott, of London, asked for permission to introduce the following resolution:

"That in view of the great amount of misery, degradation, and disease that has come upon our race from the use of alcohol, it is the opinion of this Association that it should be prescribed as seldom as possible, and with a due sense of responsibility."

The discussion following this resolution was quite animated, and the general opinion was that as much care was shown in prescribing alcohol as any other medicinal agent, and by an almost unanimous vote it was resolved to lay the resolution on the table.

Myoma of the Uterus.—Dr. Eccles, of London, opened the discussion on "Obstetrics and Gynecology" by reading a paper on this subject. The paper was an able presentation of the subject, with special reference to the most improved methods of treatment for the different varieties of tumor.

Dr. A. Macdonald, of Toronto, contributed to the discussion which followed.

Injuries of the Vaginal Outlet Occasioned by Parturition.—Dr. Howard Kelly, of Baltimore, contributed a paper on this subject. He thought that in considering the anatomical features of the vaginal outlet the physiological factors had been lost sight of. The anterior fibres of the levator ani muscle, which supports the vaginal outlet, extend to and are especially related to the support of the sides of the rectum. He distinguished between the different grades of injury to the vaginal outlet during parturition. 1. Begins at the fourchette and breaks down the lax tissue. This does not in any way affect the supporting structure of the vaginal outlet, and was therefore unimportant as far as the support goes. 2. A tear running up one of the sulci of the vagina, tongue shaped, into the vagina. This resulted from the head and shoulders of the child tearing up the tissues at the side of the levator ani. The important part of the tear lies within the vagina. This injury, which often escaped notice, should be sought out and treated at once. Bring the patient to the edge of the bed and get a thorough exposure of the

wound. Silk sutures are best, the first one passed must be in the upper angle of the wound; one or two sutures within the vagina are sufficient, and they must be passed so that the lowest and deepest part of the suture will be nearer the operator and the vaginal outlet than will be the point of entrance or exit; this tucks up the tissue in the proper manner. The common method is apt to leave a pocket or sac in the vagina, and the outlet is not properly supported. The old method also was to pass the sutures on the outer or skin surface first; this gave a good skin perineum, but a great wall is left within the vagina for secretions to collect. 3. A degree of tear which involves the integrity of the bowel, the rupture passing through the sphincter and up the recto-vaginal septum to a variable extent, and involving a tear of the levator ani fibres. This must be closed in two stages—suturing the bowel first, either by continuous or interrupted catgut sutures deeply placed. Then pass one or two silk sutures, passing them well back so as to afford good support. Silk was better to stand pressure than catgut. Then complete the operation by the superficial sutures as described, then the skin sutures. A well-performed immediate operation always succeeds in the absence of puerperal fever. It is always to be preferred; the patient is relieved from the discomfort of a second operation.

There are two important secondary operations which we have to deal with: 1. A complete tear through the sphincter; 2, where we have relaxation of the vaginal outlet.

Reference was next made to the condition known as relaxation of the vaginal outlet, which was sometimes overlooked. The anterior, posterior, and lateral vaginal walls look as if they might afford support, but to the simple touch they yield, showing that they fill up without supporting the vagina. Relaxation suspected is developed on putting the patient under an anæsthetic. Treatment must be by first denuding in the form of two triangular areas within the vagina on each side, and applying sutures in the manner described for recent tears.

Dr. Temple, of Toronto, in discussing Dr. Kelly's paper, said that he had once looked upon the perineum as a support for the uterus, but now he looked upon it as a support for the rectum and bladder. In repairing a recent perineal tear his practice had been to pass the sutures from without inward. The object in view has always been to carry the curved needle as far outward as possible, in order to get hold of the end of the divided muscle. So far his results have been satisfactory. The operation described by Dr. Kelly, the bilateral one, is an old method. If possible, remove very little tissue, as we have no more tissue than we want to restore the normal condition of the parts.

Dr. Kelly stated that whereas the genius of the whole method of operating comes from Emmet, yet recent modifications of original methods have proved of considerable value. He did not agree with Dr. Temple concerning the removal of tissue; in relaxed outlet we have more tissue than we have in the normal condition, and this must be removed.

Dr. R. A. Reeve, of Toronto, opened the discussion on ophthalmology by reading a paper on "Points of General Interest in Otology." The discussion was continued by Drs. Osborne, of Hamilton; Moorehouse, of London; and Birkett, of Montreal.

Dr. A. Stowe Gallen read a paper entitled "Medicine from a Sociological Point of View."

The Practical Bearings of Color-Blindness.—Dr. G. S. Ryerson presented a paper on this subject. He held that the examinations, as conducted for the purpose of testing for color-blindness, were often inefficient, because such conditions of the atmosphere as fog, mist, steam, etc., obscure vision, and lead to considerable variation in the powers of perception in different individuals. The test ought therefore to be applied under these conditions. People should be examined, because disease or injury may lead to impairment of the function in question. In conclusion he introduced a resolution which was passed, calling the attention of railway authorities to the serious consideration of this subject.

The report of the Committee on Necrology, referring to the deaths of several members during the year, was presented.

The Treasurer's report was received, and proved quite satisfactory.

By the report of the Nominating Committee the following officers were elected—*President*, Dr. R. A. Reeve, of Toronto; *Vice-Presidents*, Dr. F. LeM. Grassett, of Toronto; Dr. A. Groves, of Fergus; Dr. H. J. Saunders, of Kingston; Dr. G. S. McGeough, of Chatham; *General Secretary*, Dr. D. J. Gibb Wishart, of Toronto; *Assistant Secretary*, Dr. F. P. Cavan, of Toronto; *Treasurer*, Dr. E. J. Barrick, of Toronto.

MEDICAL SECTION.

Dr. Eakins, of Belleville, Chairman; Dr. Thistle, of Toronto, Secretary.

The Diagnosis of Typhoid Fever.—Dr. J. E. Graham, of Toronto, presented a paper with this title. He first alluded to the importance of early and correct diagnosis in this disease, in the proper management of which so much depended. The differential diagnosis of tubercular meningitis in children, acute tuberculosis, and typhoid, was carefully pointed out and cases cited to demonstrate the different points alluded to. The renal mask sometimes assumed by the disease was carefully referred to, and the importance of distinguishing from nephritis was emphasized. The relation of typhoid to pneumonia and the presence of the latter, particularly in the earlier stages of the fever, was illustrated by brief clinical records. To distinguish malarial remittent fever from typhoid was sometimes difficult, but careful examination of the blood, taken during the paroxysm, with a high-power microscope, would reveal the presence of the plasmodium malariæ. Pyæmia was also sometimes difficult to distinguish from typhoid. The presence of bacilli in the blood, the use of Ehrlich's urine test, would help in the diagnosis. The urine or blood from the roseola might be examined for the typhoid bacilli. Puncture of the spleen of a typhoid patient to procure a sample of blood was not permissible, although it had been done by several German physicians.

Dr. McPhedran, of Toronto, after alluding to the difficulty in distinguishing between typhoid and tubercular meningitis in children, referred to the abortive cases of what was seemingly typhoid, but where Ehrlich's test failed. The discussion was continued by Dr. Sheard, of Toronto, and others.

Is Alcohol a Stimulant?—Dr. H. Arnott, of London, deprecated the habit of many practitioners in prescribing alcohol as a stimulant, and expressed his conviction that mistaken ground had been taken by the profession in regard to the value of alcohol as a therapeutic remedy to combat disease. In the brief discussion which followed, the strongest exception was taken to the views expressed by the paper.

Epileptic Insanity.—Dr. I. Millman, of Toronto, followed with a paper on this subject. After pointing out the different forms of epilepsy, with the symptoms characteristic of each, he referred to the importance of recognizing that form known as petit mal, which too often escaped notice and treatment. He instanced important cases where he believed crime had been committed while suffering from the influence of petit mal, although the public might be slow to believe the culprit was not responsible for his deed. He placed a high value on the efficacy of the bromides in epilepsy, and sometimes combined cascara sagrada to overcome the tendency to constipation in the use of the former.

A Narrow Prepuce and Preputial Adhesions in Childhood.—Dr. R. W. Bruce Smith, of Seaforth, narrated histories of some cases occurring in his practice, in which convulsions were quite frequent despite the use of bromides, etc. The children had apparently become chronic epileptics. After dilatation in one case, and circumcision in another, the convulsions disappeared completely. In each case the glans penis was firmly bound down by the closely adherent prepuce, and behind the glans was found a hard, foul smegma which had doubtless been a constant source of irritation. Reference was made to other cases of the same nature which Dr. Smith had reported at a previous meeting, which have continued to do well and have had no return of the distressing nervous symptoms, complained of. He urged the importance of careful examination of the genitals in boys manifesting nervous symptoms, and while deprecating any operation where the cause was due to some lesion in the brain or spinal cord, he expressed the conviction that frequently a causative relation might be traced between certain distressing nervous phenonoma and an abnormal condition of the penis.

Dr. Howitt, of Guelph, in the discussion which followed related several interesting cases which had come under his observation, of an exactly similar character, and which had been relieved in the same way.

Dr. A. B. Osborne, of Hamilton, read a paper on "Pathological Weeping."

Phlegmasia Dolens.—Dr. McWilliams, of Thamesford, presented the histories of five cases of this affection treated chiefly by salicylate of soda, in which recovery had occurred more quickly than usual.

Dr. Adam Wright also read the history of a case of the same disease. He considered the salicylate of soda a valuable remedy, but found the weakness and depression of septicæmia contra-indicated its use. His great objection to it was the nauseating effect it produced on the patient. Opium, while harmful in cases of septicæmia, was, he thought, the best remedy to quickly relieve the pain of phlegmasia dolens. Purgation by small doses of Epsom salts and supporting tonics was the treatment he would recommend. In conclusion Dr. Wright emphasized the importance of observing the strictest antiseptic precautions in the practice of obstetrics, and with such strict precautions expressed the opinion that the diseases of the puerperal period would seldom occur.

Dr. Barrick, of Toronto, considered that opium should be the mainstay in phlegmasia dolens.

Dr. Cronyn, of Buffalo, while favoring the use of the salicylate of soda, said its nauseating properties might be greatly lessened, if not entirely removed, by combining it with the aromatic spirits of ammonia and Battley's solution of opium.

Dr. J. Gardiner, of London, presented a paper on "Pelvic Cellulitis."

Dr. H. A. Macallum, of London, read a paper on "Some Points in the Pathology of Kidney Disease," which was discussed by Drs. John Caren, McPhedran, Sheard, J. E. Graham, and others.

SURGICAL SECTION.

Dr. Grassett, of Toronto, Chairman; Dr. Primrose, of Toronto, Secretary.

Early Resection vs. Conservative Treatment in Coxitis.—Dr. H. Mynter, of Buffalo, N. Y., read a paper with this title, and was followed by Dr. G. A. Bingham, of Toronto, with one on "The Surgery of Tuberculosis."

Dr. Mynter commenced by giving a history of the nature and symptoms of the disease, and discussed the advantages of the different forms of treatment, emphasizing the importance of early operation as the only means by which the progress of the disease might be arrested.

Dr. Bingham referred to the importance of early diagnosis in tuberculosis. So long as the disease does not proceed unfavorably, rest is the chief thing. Caseation may, however, occur, and operation becomes necessary; the disease must be entirely eradicated, whatever method we employ. We are led to conclude that in certain cases rest, constitutional and hygienic treatment, will prove efficient. If caseation has occurred and the disease has extended beyond the articular ends of the bones, erasion should be done. If confined to the synovial membrane aspiration will suffice, and if the disease is very definitely localized it may be removed by the sharp spoon. Early operative interference undoubtedly shortens the suffering.

Dr. McFarlane, of Toronto, in the discussion following the above papers, referred to the dispute as to the starting-point of the disease; as to whether it was in bone, cartilage, or synovial membrane. In the hip the disease might first arise in the ligamentum teres. He alluded to a case at present under his care in Toronto General Hospital, a boy suffering from acute osteo-myelitis which began in the ankle. The tender and swollen part had been cut down upon, and the diseased bone scraped out, and very shortly afterward a similar condition developed below the knee-joint, which was similarly treated. The child was now improving. Conservative treatment would often arrest tubercular disease, and therefore he was not inclined to open the joint early. Complete excision was, however, safer than erasion, because of less likelihood in the former of any diseased tissue being left behind.

Dr. B. E. Mackenzie, of Toronto, narrated the case of a small lad in whom he had successfully removed a small tubercular focus from the head of the tibia. The joint trouble usually arises in the bone. True conservative treatment is that of rest for the part when the nidus is confined to the bone, rather than after the joint has become affected. Referring to a case mentioned by Dr. Mynter, he thought it unlikely that operation could be deemed necessary four weeks after the commencement of the tubercular inflammation. Fixation of the joint may be complete, and at the same time the patient may be allowed to move about. Statements of cases dismissed as "cured" in two or three weeks, are fallacious. He did not consider a case could be considered as cured until two or three years have elapsed. Care must be shown in providing proper mechanical apparatus after operation, in order to prevent relapse.

Dr. Bingham, in closing the discussion, spoke of the confusion in the minds of some as to the meaning of a "cure." A tubercular focus may become encapsuled and lie quiescent, but it is liable at any time to light up to activity.

Dr. Burt, of Paris, read a paper on "Short Notes on Injuries of the Skull, and Epithelioma of the Larynx."

Dr. Primrose, of Toronto, presented a paper on "Fatty Tumors in the Inguinal Canal."

Lithotomy.—Dr. Grassett, of Toronto, then followed with a paper on this subject. He discussed the advantages of the different methods of operation, and thought the dangers in the lateral operation had been exaggerated. His experience had been quite satisfactory with the lateral incision, and while the prospect was that in the future the supra-pubic operation would be the more popular, the results with Toronto surgeons had been favorable to the lateral method. He related several exceptions where the supra-pubic was considered the safer, and in the cases of large calculi there was more room with that operation. Improved methods of diagnosis, however, rendered the early recognition and treatment of calculus such that much less time was lost than formerly in giving relief in these cases.

Dr. Holmes, of Chatham, said he had hitherto been satisfied with the results in the lateral operation.

Dr. Eccles, of London, thought that the recent advance in abdominal surgery had done much to develop, and perhaps popularize, the operation of supra pubic lithotomy. He narrated the histories of several interest-

ing cases in which he had performed that operation for the removal of calculi.

Digital Exploration of the Female Bladder.—Dr. James F. W. Ross, of Toronto, presented a note on this subject. The method advocated was by the use of the little finger, the other fingers being flexed on the palm, the patient lying on the back with the limbs drawn upon the abdomen. The urine was first drawn off. If the tip of the little finger would not readily enter, rapid dilatation with Ellinger's or Palmer's cervical dilator to a very limited extent might be secured. The pain was not excessive. By this method the little finger could be passed into the bladder, the orifices of ureters be felt, and thorough exploration of the bladder secured.

Dr. Howard Kelly, of Baltimore, stated that he had practised that method for several years. The little finger, as stated by Dr. Ross, is preferable to the index-finger. If the index-finger be introduced with the pulp down the second finger strikes against the pubic arch and is limited in that way; the little finger, however, introduced in the same way will permit of invagination of the soft tissues by pressure of the other fingers, and thus length is added to the digit. The tactile sense seems sufficiently acute in the little finger. Dr. Kelly said he often made two small lateral clean incisions at the meatus, and subsequently closed these by suture. The bimanual method should of course be used in all cases of exploring the bladder.

Dr. Price Brown, of Toronto, read a paper on "Deviations of the Nasal Septum."

Talipes Requiring Operation.—Dr. B. E. Mackenzie, of Toronto, presented four cases illustrating the surgical treatment of this deformity. The method of Phelps, of New York, was referred to. He recommended great care in first correcting the varus before attempting to remedy the equinus. Phelps's operation of incision on the concave surface of the foot was described, and shown to be better than removing bone on the convex side. The foot should first be brought into a position of over-correction, and retained there by fixation apparatus, preferably plaster bandage.

Dr. A. E. Mallock, of Hamilton, read a paper on "Excision of the Shoulder and Elbow Joints on Same Arm for Traumatism." He related the history of a highly interesting case, demonstrating how useful a limb might be obtained after such an extensive mutilation.

Acute Necrosis of Growing Bone.—Dr George A. Peters, of Toronto, presented a paper on this disease, which is known also as acute infective osteo-myelitis, necrosial fever or bone-typhus and is exceedingly malignant and more frequently recognized at the post-mortem table than at the bedside. The symptoms were illustrated by the history of a typical case.

Therapeutic Hints.

On the Value of Arsenic.—Mr. Jonathan Hutchinson believes that arsenic is a specific for psoriasis, pemphigus, and recurrent herpes. It sometimes acts badly in aged and elderly persons. It is of doubtful value in eczema.

The Composition of Tuberculin.—The *Deutsche Medicinische Wochenschrift* announces, apparently on the best authority, that Professor Koch, since his return from Egypt, has been principally engaged in isolating the active principle of tuberculin, and defining its chemical characters, so as to make it possible to test its properties in the same way as is done in the case of other medicinal substances. As soon as these researches have been brought to a successful issue—a result which there is reason to hope will be attained within the next few months—Professor Koch will publish a comprehensive work in which full particulars will be given, not only of these later investigations, but of the whole procedure used in the preparation of the remedy.

Reduction of Colles's Fracture Under Anæsthesia.—Dr. R. C. Huse, of Georgetown, Mass., writes: "I have noticed quite frequently in the various journals, in allusion to the treatment of Colles's fracture, that the writers advise the doing away with splints, complete reduction being the one thing essential to success. With that idea I am much pleased, but I wish they would go a little further and use an anæsthetic, and see how much easier this is accomplished, and consequently how little effusion takes place; for much of the latter comes from the violent effort necessary in restoring the parts to their proper place. As this fracture is a *divulsion* of the head of the bone from the shaft, the restoration of the parts under an anæsthetic is so easy that they will fall in place by the simple grasping of the hand, as in shaking. If, therefore, reduction is all that is necessary, add the anæsthetic, and pain and deformity following the fracture will be the exceptions."

Cocoanut a Remedy for Tapeworm.—Dr. Charles E. Denhard, of New York, says: "I have seen some good results from the use of cocoanut for tapeworm. Sixteen years ago Mr. H—— came to me for treatment of tænia, which was only partially successful. Five months later he came to my office with two tænias (two heads and all), which were expelled as a result of eating for two days nothing but cocoanut. I have since seen several cases of successful expulsion after the same treatment, but it is by no means always efficacious. Ethereal fluid extract of male fern (Merck's) takes the first rank, but it must be given in large doses (not less than ʒ iij. or ʒ iv.), of course one such dose only."

A Disordered Condition of the Primæ Viæ.—Dr. J. M. Hays, of Oxford, N. C., writes: "A furred tongue—large and flabby, with a bluish cast—anorexia, constipation, perhaps alternating with diarrhœa, slight headache, general lassitude, sleeplessness, loss of interest in business and pleasure. Do you see such cases? Give them

℞. Podophyllin..... gr. x.
Tinct. nux. vom..... ʒ j.
M. Sig.: Shake and take from five to eight drops in a little water before each meal.

You will be pleased with the results. Use this also where nitromuriatic acid seems indicated, but fails to produce the desired result. After an experience of several years with this prescription I can recommend it with confidence."

Katzenjammer.—Resorcin is said to act admirably in cases of nausea and depression following a carouse. It is given in the dose of from five to ten grains in plenty of water flavored with syrup of orange peel, and may be repeated once or twice at intervals of half an hour. A single dose of ten grains is, however, said to be usually sufficient.

Square Sounds in Stricture of the Deep Urethra.—Dr. Hal C. Wyman, of Detroit, employs sounds made square (slightly grooved between the angles for carrying a lubricant), in the treatment of deep strictures, and says that they have given him great satisfaction. He has them made of copper, of the varying sizes of the American scale, and coated by first dipping them in metallic mercury and then rubbing them until they are highly polished. The principle upon which they are employed is that of the wedge.—*International Journal of Surgery*, June, 1891.

Vomiting of Pregnancy.—Drs. Heuske and Gottschalk have found menthol very useful in obstinate vomiting of pregnancy. They give the drug according to the following formula:

℞. Menthol..... gr. xv.
Alcohol..... ʒ v.
Distilled water..... q. s. ad ℥ v.
M. Sig.: Tablespoonful hourly until the vomiting ceases.

In several instances in which the vomiting had refused to yield to any other remedy, it was controlled after the fourth or fifth dose of this solution.

Flatulent Dyspepsia is often greatly relieved by a mixture of equal parts of powdered sulphur, magnesia, phosphate of lime, and charcoal. A teaspoonful of this powder is taken in a glass of water during an attack.

Sterility.—Not infrequently sterility in women depends upon an acid condition of the vaginal secretions. In such cases a vaginal douche at bedtime of two quarts of water, containing one ounce of bicarbonate of soda and three or four ounces of glycerine, will often lead to the desired result.

The Preparation of Museum Specimens.—Dr. Richard Thoma, of Dorpat, describes a method he has devised for retaining the natural color of organs in museum preparations. After slight washing in water they are placed for some hours in strong saline solutions, of which he gives two formulæ :—

	A.	B.
Crystallized sulphate of soda	100 grm.	60 grm.
Chloride of sodium	100 grm.	100 grm.
Chlorate of potassium	100 grm.	30 grm.
Nitrate of potassium	10 grm.	10 grm.
Water to make	1 litre.	1 litre.

The organ is suspended for eighteen to twenty-four hours in one of these solutions, and then placed in pure spirit, which requires changing once or twice. It is better to immerse only portions of the larger organs, such as the liver or spleen. The preparations retain their appearance for months, the only notable change being the conversion of the red color of hæmoglobin into the browner tint of methæmoglobin. Nor is their structure so affected as to be unfit for subsequent microscopical examination.—*Lancet*, June 6, 1891.

Acne.—The following is recommended as a useful application in cases of blackheads and pimples disfiguring the faces of the young, of both sexes :

℞. Oxide of zinc,
Resorcin,
Starch ..... āā ʒj.
Vaseline ..... ʒijss.
M. Apply a thin coating to the affected parts, at bedtime, and rub off with oil the following morning.

An Internal Angular Arm Splint.—Dr. G. M. Randall, of Augusta, Me., writes : "From the fact that there are so many varieties of splints used about the arm and forearm, it would seem that just the thing had not been found. All of the many indications may not be met by any single appliance, but the splint herein described meets more indications than any other one splint I have yet seen. It is made of medium heavy tin-plate, in three pieces, so cut that when soldered and riveted together and applied, the proximal arm of the splint covers the anterior surface of the biceps, while the distal arm covers the flexor muscles of the forearm at the same time it puts the arm at a right angle and midway between pronation and supination. There is a wooden handle at the distal end which serves as a grip. The splint could easily be made with a hinge-joint and thus any degree of angle could be obtained. The advantages of the position of semipronation are obvious, but it is well to mention that it is a natural restful position. The splint is well adapted to fractures of the external or internal condyles, any fracture of the humerus below the upper third, or any fracture of the radius or ulna including Colles's. I have used the splint with success in a case of compound complicated fracture of the internal condyle, and in Colles's fracture, and have also found it of service in retaining the arm of a child with fractured clavicle."

Piperazine is the name of a newly-introduced drug which, it is claimed, exerts a beneficial action in uric acid gravel and gouty affections. In *Notes on New Remedies* it is stated that the hydrochlorate of piperazine is preferred by most practitioners, and it is further suggested that the remedy is most advantageously administered in combination with aërated water.

Lysol is a new antiseptic that has been taken up with enthusiasm in some of the continental cities. It is a clear oily liquid, with a strong pungent odor, and often exerts an irritant action on the skin.

Acute Coryza.—Dr. M. D. Lederman, of New York, finds the following mode of treatment very beneficial during the congestive stage of an acute nasal catarrh. The nasal chambers are sprayed with any of the antiseptic solutions, Seiler's preferred, until they are sufficiently cleansed, and then the following solution is used :

℞. Cocaine,
Menthol ..... āā gr. xx.
Benzoinol ..... ʒij.
M. Ft. solution.

The feeling of fulness in the nose, associated with the dull frontal headache, is no doubt the result of extreme congestion. For the relief of these symptoms, cocaine has been used for a considerable period, but it has been found that its effect soon passes off, and the patient is left in the same uncomfortable position as before. To obviate this menthol was added to the solution. Menthol is a local anæsthetic, and in combination with cocaine, it keeps up the local depletion and leaves a pleasant coolness in the nasal chambers, enabling the patient to breathe through the natural passages. Benzoinol is used in this solution as the menstruum, on account of its bland and unirritating qualities, and freedom from unpleasant odor.

A Dental Screw for Removing Impacted Bullets.—Dr. W. L. Hughlett, of Cocoa, Fla., writes : "Isaac H——, a young negro man, came to me on March 31st last, to be treated for a gunshot wound of the right elbow which he had received two days previous. He had been shot from behind with a 38 calibre pistol, the ball having penetrated the skin a little above the joint, passing downward and forward, lacerating the ligaments and synovial membrane, and splintering the bones to some extent, and was firmly impacted between the internal condyle of the humerus and the olecranon process. The arm was so much swollen that I decided to chloroform the man before making any effort to extract the ball. This done, I carefully opened up the tract and attempted with forceps to remove the bullet, but it could not be moved. I tried a pair of long shank toothed forceps, they only cut through the lead without loosening the ball a particle. Having seen Dr. L. T. Daniel, a dentist having an office adjoining mine, extracting roots very skilfully with a dental screw, I thought I would have him try it on this ball. Calling him and his instrument to my assistance, I opened up the wound ; he drove in the screw and extracted the ball in a few seconds, without trouble. I hardly hoped for anything but an anchylosed joint, but the wound has healed, there is good motion, and the arm is quite as useful as ever."

Eczema.—Unna recommends the following application for the relief of obstinate eczema of the scrotum and anus.

℞. Iodoformi ..... ʒij.-iv.
Zinci oxidi ..... ʒjss.
Aq. calcis,
Ol. lini ..... āā ʒjss.
M. Sig. : For external use.

For Tender Feet.—Tramps, either amateur or professional, who suffer from sore feet after an unusually long walk, will experience great relief from soaking the feet once or twice a week in a half-pailful of hot water to which a piece of nitrate of potassium the size of a small walnut has been added.

Vinegar for Urticaria.—After trying many remedies in a severe case of urticaria, Mr. Swain found a vinegar lotion gave almost instant relief, and subsequent trials in other cases have been equally successful. One part of water to two parts of vinegar is the strength most suitable.—*British Medical Journal.*

Pistoia Powder.—There is a powder made in a convent near Pistoia, Italy, which is used very extensively as a protective against gout. The following is said by Mr. Chastaing to be its composition.

℞. Bryonia root,
Gentian,
Chamomile.....āā gm. x.
Colchicum root..... gm. xx.
Betony..... gm. l.

This is made into 365 powders, one of which is taken each day of the year in a full glass of cold or hot water.

The Control of Hemorrhage in Amputation at the Hip-joint.—Dr. Neal Hardy reported in the *University Medical Magazine*, for May, 1891, a case of successful amputation at the hip joint in which hemorrhage was controlled by direct digital compression of the aorta, effected by means of a preliminary laparotomy. Dr. John J. Buchanan, of Pittsburg, writes in the same journal for July, claiming that the idea was his own, and that he had made and published the suggestion some time before the operation was performed.

Œdema of the Glottis.—Dr. de Mendoza has successfully treated three cases of severe œdema glottidis by means of hypodermic injections of pilocarpine. The dose was $\frac{1}{15}$ grain, and three injections were given within an hour.—*Semaine Médicale.*

To Abort a Furuncle.—The early application of the ointment of the nitrate of mercury is recommended as an effective means of aborting a boil.

Amenorrhœa.—The following is recommended as a reliable emmenagogue in many cases of functional amenorrhœa:

℞. Bichloride of mercury,
Arsenite of sodium.....āā gr iij.
Sulphate of strychnine..... gr. jss.
Carbonate of potassium,
Sulphate of iron. .....āā gr. xlv.

Mix and divide into sixty pills. Sig.: One pill after each meal.

—*Revue Médico-Chirurgicale des Maladies des Femmes.*

Gonorrhœa.—Rademacher recommends an injection of five minims of pyridin in three ounces of water as the most efficacious of all local remedies for gonorrhœa.

Benzin for Boils.—Dr. F. W. Langdon uses benzin as an abortive agent in furunculosis, employing it in the following manner (*Lancet-Clinic*): At the first appearance of the little hard painful papule, saturate a pledget of absorbent cotton with the remedy, and press it firmly, but not forcibly, over the swelling, for about half a minute. Repeat this every hour or two for the first day, after that two or three times a day, as the swelling and pain subside.

New Instruments.

TWO NEW EYE INSTRUMENTS.[1]

By J. S. PYLE, M.D.,
CANTON, O.

In attempting to introduce anything new to a large number of liberal-minded men such as are found in the medical profession, it is perhaps unnecessary to offer an apology; but as the medical profession, like all other professions and organizations, has among it a class who protest against innovations, it would appear appropriate that I offer some excuse for allowing myself to occupy the position I have chosen. Knowing how the profession is constantly being annoyed with new devices, I should be the last to claim your indulgence, were it not that I feel confident I have something to present worthy of consideration. Still, should I fail in my anticipations, I request nothing more than the charity that courtesy so generously bestows. On the other hand, if I succeed, the pleasure of realizing that fact is all I could ask.

I might state, with advantage, that the labors of an oculist are not always surrounded by conveniences; and as many of us are often called from a distance with a view of making some delicate operation upon the eye where a suitable assistant cannot be had, it is not at all surprising

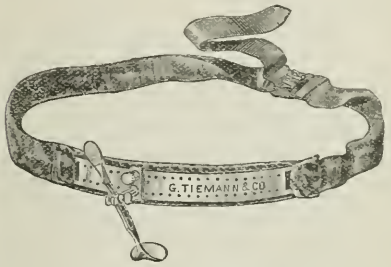

Fig. 1.

that one would be forced to plan some arrangement by which the aid of another could be dispensed with advantageously. In pursuance of this object, I have devised two instruments, both of which are familiar; but so differently arranged, and in some respects constructed, that I am almost justified in calling them original.

Fig. 1 shows a view of my Self-retaining Lid Retractor. It consists of a thin piece of flexible steel equipped with a slide, which bears at its lower part a clamp projecting about an inch forward.

The jaws of the clamp are slotted, and have a common base; but sufficiently separated to receive between them a modified retractor, or elevator. The handle of the retractor is slightly curved, and also slotted, for the purpose of giving passage to a thumb-screw, which is used to pinion it at whatever angle and point of elevation it may be deemed necessary. The base of the clamp operates upon a pivot, which gives it lateral motion, and allows the retractor to conform to the direction of the tension of the eyelid. The steel front bearing the slide is padded, and provided with a perforation at each end, through which is fastened a silk band, made to encircle the head and retain the instrument in position. The slide referred to can be moved along the steel band, and permanently fixed at any point desirable. This makes it universal, and equally useful for either eye. When adjusting the instrument, the operator should bear in mind to place the steel front just above the superciliary prominences, and tighten the silk band sufficiently to prevent any downward movement. This observed, the slide bearing the clamp and retractor may then be moved to a point immediately above the eye to be operated upon, and secured there by a friction-screw provided for the purpose. When ready to proceed with the operation, the retractor should be gently introduced, elevated, and pinioned at the point desired. The discomfort arising from its use is very slight, and a little acquaintance with the instrument is all that is necessary to prove its superiority in the cases for which it was designed.

The purpose of the instrument is to do away with the stop-speculum in cataract operation and in iridectomies, and the necessity of having an assistant to hold the ordinary lid elevator. It is the writer's opinion that it is impracticable and unsatisfactory in many cases to use the common stop-speculum. For instance, where the palpebral fissure is short, or the eye sunken very much in the orbit, a speculum compromises the ease of approaching the ball; and if the patient be nervous and inclined to blink, its removal after the operation is attended with not a little danger. I have of late discarded the use of the stop-speculum, and used exclusively the ordinary lid elevator, which I have found to be much more satisfactory, owing to its ease of introduction and removal, and the

[1] Read before the Canton Surgical and Pathological Society, January 5, 1891.

readiness with which the eye can be reached from the side.

The fact that the elevator has proved superior in my hands, caused me to plan how it could be used without the aid of an assistant. This I believe I have successfully accomplished, and trust that my ideas may be found in harmony with the views entertained by others on this subject.

Fig. 2.

Fig. 2 represents my Fixation Forceps, to which I wish to call special attention. The jaws, as you will observe, form a segment of a circle, corresponding to that which the eye describes behind the corneal limbus. The advantage of this over other fixation forceps is evident. A larger amount of conjunctiva can be seized, and the eye embraced in such a manner as to effectually prevent the ball from rotating in the horizontal or vertical axis. This, experience teaches, is greatly to be desired in cataract operations, and particularly in those cases where the anterior chamber is shallow, and a well directed section is imperative. With the ordinary fixation forceps, every operator on entering the knife has had the unpleasant experience of seeing the globe move about as though meeting with no resistance whatever; and in many cases, where there is a very loose conjunctiva to deal with, the eye turns upon its horizontal axis until the point of puncture is almost vertical before the knife can be forced through the coats and made to traverse the anterior chamber. As soon as the resistance is overcome, the eye returns to its former quiescent position, and on so doing prolongs the operation, which at this time it is so necessary to hasten, owing to the escape of aqueous and the importance of securing the counter puncture before the cornea sinks sufficiently to embarrass the passage of the knife. Delays are sometimes hazardous, and the operator is frequently compelled to hurry, without proper deliberation, and under circumstances that make success an accident rather than the result of any well-directed method.

If, then, it is possible to minimize the mobility of the

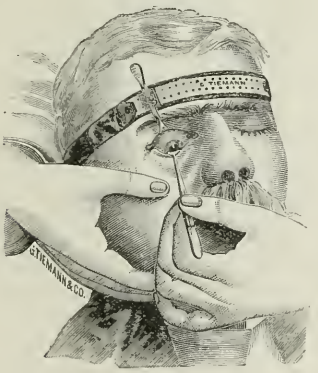

Fig. 3.

eye during the process of making the section, it seems plain that an essential point is gained, and what before was an exceedingly risky proceeding is turned into a very simple one.

Fig. 3 shows both instruments in position. The illustration does not, however, give the correct position of the jaws of the forceps upon the eye, as they should be applied to the ball behind the corneal limbus; but in every other way it is well executed. The sphere of usefulness of both instruments is not confined to cataract extractions; but they may be used equally advantageously in iridectomies, the operation of discission in congenital cataracts, secondary cataract operations, and other operations where an easy approach and immobility of the ball are to be desired.

In leaving this subject to the consideration of my professional friends, I only hope that I may not have occupied your attention in vain; but that the ideas advanced may prove a source of usefulness.

I desire to express my obligations to Messrs. George Tiemann & Co. for their excellent work in making the instruments, and preparing the illustrations.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 19, 1891, to July 25, 1891.

Robertson, Reuben L., Captain and Assistant Surgeon. Ordered for duty to Fort Niagara, N. Y., on the abandonment of Fort Abraham Lincoln, N. D.

Kneedler, William L., Assistant Surgeon. Granted leave of absence for one month.

Tilton, Henry R., Surgeon. Granted leave of absence for two months on surgeon's certificate of disability.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 25, 1891.

Field, James G., Assistant Surgeon. Ordered to special duty in the Bureau of Medicine and Surgery.

Hope, James S., Assistant Surgeon. Ordered to the receiving ship Franklin.

Morris, Lewis, Assistant Surgeon. Ordered to the Ajax and other monitors, Richmond, Va.

Keeney, James F., Assistant Surgeon. Promoted to Passed Assistant Surgeon.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 25, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	41	10
Scarlet fever	117	18
Cerebro-spinal meningitis	1	1
Measles	165	16
Diphtheria	58	24
Small-pox	1	0
Varicella	0	0
Pertussis	1	2
Erysipelas	0	0
Mumps	0	0
Rötheln	0	0

Arsenic in Wall-paint.—Dr. William N. Swift reports a case of chronic arsenical poisoning in the *Boston Medical and Surgical Journal*, in a child, the source of which was found to be in the blue paint on a wall.

Illiterate English Surgeons.—It seems rather strange, after all that our English friends have had to say about the illiteracy of physicians in this country, to learn, on the authority of Sir Ralph Thompson, that there is a "manifest deficiency in orthography prevalent among the young medical officers of the army."

Metamidophenylparametoxiquinoline is the name of the latest rival of quinine. It has been suggested as a remedy for stuttering.

THE PATHOLOGY OF THE CAISSON DISEASE.*

BY HOWARD VAN RENSSELAER, PH.B., M.D.,

LECTURER ON MATERIA MEDICA IN THE ALBANY (N. Y.) MEDICAL COLLEGE.

ACCURATE scientific observations and records of the symptoms and lesions from which men suffer who work in compressed air are of quite recent date, though more or less incomplete and fragmentary accounts of the pathological effects upon workmen under increased atmospheric pressure have been handed down to us for three centuries or more.

The severity of these symptoms has steadily increased in direct ratio to the greater pressure which the human system has had to withstand, on account of the greater requirements in engineering science.

The first experiment that has been recorded of the employment of compressed air occurred in the beginning of the sixteenth century, when two Greeks, in the presence of Charles V. and several thousand spectators, let themselves down under water in a large inverted kettle and rose again without wetting themselves.

From this epoch the diving-bell, which was unventilated, slowly increased in favor and use. The pathological effects in the divers that have been mentioned by various writers of these times were mostly of a trivial character, and were rightly thought, in part at least, to be due to the moisture, heat, and foul air in the bells.

John Smeaton,[100, 101] in 1678, introduced fresh air in the bells by means of the air-pump. From this time most of the symptoms which had been observed in the unventilated diving-bells suddenly ceased.

The first physicians to call attention to the pathological symptoms on workmen were Hamel,[56] in 1820, and Colladon,[26] in 1826.

Neither saw marked cases of the disease, and what symptoms they did see—excepting of course the pain in the ears, which they rightly attributed to direct pressure of the condensed air on the membrana tympani—they considered to be of a neuralgic character.

Triger,[110] in 1848, and Barella,[2] in 1861, thought that the pains were of a rheumatic nature, and were produced by the rapid chilling of the air when the pressure in the bells was removed, on workmen tired and bathed with sweat.

Pol and Watelle,[76] published their report in 1854. Their article is the first of any real scientific value, from a medical stand-point, that has appeared; and they were the first to see the disease in all its intensity.

Since that time many monographs have been written on this subject, and a multitude of cases published. These reports having been printed in many languages, over a long series of years, and often in not-widely circulated journals, appear to have been little known by the various writers on the subject. So that nearly every observer has developed a theory of his own, and has paid but scant or no attention to those of others. Of all the reported cases of death from this cause, there have been but twenty-nine on which an autopsy has been made, and, strange to say, there are two cases only on record in which the spinal cord has been examined microscopically.

The objects of this paper then are, first, to report two cases of caisson disease, one terminating in recovery, and the other in death, and in which latter an autopsy and a minute examination of the cord were made; and second, by a critical examination of all the theories, and all the necroscopies, to endeavor to throw a little more light on this obscure subject.

CASE I.—M. McD——, American; single; laborer. Entered St. Peter's Hospital, October 1, 1889. Patient's family history is good. He has always been perfectly healthy. He has never indulged to excess in alcohol, and has never had any venereal disease. In June, 1888, he worked for about two weeks in a caisson at Cairo, Ill., the pressure in the caisson being about forty pounds, and the shifts of two hours length. From this he felt no ill effect. On the day in question a new caisson was employed, but he does not know whether the pressure was increased or not. As usual, on this day he worked his two-hour shift, and on emerging from the caisson he drank some coffee, took a hot bath, and entered a boat to be carried across the river. On trying to rise from his seat—this being half an hour after coming out of the caisson—he found that he was unable to move his legs and they felt numb. He had to be carried to the hospital. He had no nausea, no giddiness, no pain in the legs, but some pain in the belly which lasted five minutes. He became obstinately constipated, which symptom has always continued. Retention of urine occurred at once, and lasted three months, and was followed by incontinence which continued a month; then he gradually regained control of his sphincter, and now he can hold his water for two hours.

For the first week his legs were completely paralyzed. Then he began to move slightly the toes of his left foot, then the knee of the same leg. His right leg then began to improve in the same way; after four months he was able to walk with crutches, after six months he could get along with two canes instead of the crutches, two months later he was able to get about with one. During this time he had some girdle sensations around his abdomen of no great severity. He was treated at the hospital with electricity and liniments.

Since he left the hospital he slowly improved for some time, but now seems to be at a standstill.

Physical Examination.—Patient is fairly nourished, no œdema. There are no cardiac nor thoracic lesions. The patella reflexes are markedly exaggerated, ankle clonus can sometimes be feebly obtained, the other reflexes are normal. Tactile sensation and sensations of heat and cold are normal. His gait is staggering, and he is unable to walk without a cane. He cannot jump. The legs cannot voluntarily be flexed above an angle of forty-five degrees. His bowels move after the exhibition of strong medicines only. Water can be retained for three hours. Urine, amber-colored, acid, specific gravity 1.020, contains no albumin, and is microscopically negative. Ordered galvanism to his legs every day, and a pill containing small doses of strychnine and belladonna.

November 1st.—Patient can hold his water now for four hours, and he has to get up two or three times at night. He can jump about an inch high, and can flex his legs more than last month. He can now walk without a cane, but it is with considerable effort. His bowels are not quite so constipated as before.

* Being the Merritt E. Cush Prize Essay of the New York State Medical Society, 1891.

December 1st.—His control over his bladder is much stronger; he is able to hold his water for five hours, and has to get up once during the night only. Constipation continues much the same. He jumps now fairly well, and walks with scarcely any staggering. He can flex both legs well, the left being somewhat stronger. The patella reflex is still markedly increased, and sometimes he has girdle sensations, which, however, are not very marked. His general condition is much improved.

March 1, 1890.—Since last note patient has improved slowly, and now can walk quite well.

Case II.—J. M——, aged forty-eight; American; single; a boatman by occupation. Entered St. Peter's Hospital September 15, 1889.

History.—Patient's sister, brother, father, and uncle on the father's side died of consumption. He has a strong alcoholic habit. He had well marked syphilis three years ago. He was well till September 8th, when with a companion he went down, from curiosity, into a caisson under the Hudson River, at Hoboken. This was the first time that either had been in a caisson; they did no work there, but remained in the compressed air about half an hour. The amount of pressure and the time of locking-in and locking-out were unknown. On emerging his companion had pain in, and bleeding from, the ears, but no other symptoms. Our patient felt weak, dizzy, nauseated, and had ringing in the ears. He walked at once to his boat, a distance of about fifty yards, and went into the cabin. There his legs suddenly became weak and could not support him, and he fell to the floor. He did not lose consciousness, and had no pain in the head, spine, nor legs. He was unable to move his legs, and had to be carried to bed, where he has been ever since. From that time he has been unable to move the lower half of his body, or to pass his water; he has had no erection, and no movement of the bowels.

Physical Examination.—Patient is well nourished, and has no œdema. His temperature, respiration, and pulse are normal. There is no evidence of pulmonary nor cardiac lesion. There is complete paraplegia below the waist. Epigastric, cremasteric and patella reflexes are absent. Plantar reflex is faint on the left side, absent on the right. There is no ankle clonus. When touched he can feel and localize the object when the pressure is firm. With the æsthesiometer he is unable to distinguish between one or two points, even at a distance of 10 ctm., on any place on the thigh, leg, or foot. He is unable to distinguish between the scratch of a pin and the friction of a broad feather. He cannot tell the difference between hot water and ice. There is a commencing bedsore on each side of the sacrum. It requires an electric current of twelve milliampères to produce a faint contraction of the peronei or tibialis anticus of either side. Urine, red, opaque, alkaline, specific gravity 1.025. Very foul smelling. Contains five grammes of albumin to the litre. (Esbach's albuminometer used.) Microscopically, there are found a large number of red blood-cells, pus, and bacteria. No casts could be found. Ordered strychnine (gr. $\frac{1}{30}$) t.i.d. Bladder to be washed daily with acid carbolic, 1 to 500. Galvanism every day to legs.

September 19th.—Patient's bowels move only after exhibition of large doses of cathartics. When he has a movement it is involuntary. He complains of a girdle sensation around the waist

September 21st.—He can now move the toes of his left foot, and very slightly the ankle; he can also move slightly the toes of his right foot. Urine, red, opaque, specific gravity 1.020, alkaline, contains three grammes of albumin to the litre. Blood- and pus-cells are numerous, no casts; it swarms with bacteria. It does not now smell quite so foul as at last note, and contains less blood and albumin.

September 23d.—His bedsore is washed and dressed every day, but is rapidly extending. He has been put on a rubber ring. Until to-day his water has had to be drawn off every eight hours; this morning he passed it involuntarily.

September 27th.—It is found that his bladder can hold his water about an hour, and then it is passed without the patient's knowledge, as are also his fæces. His appetite is good, and he can move his toes and feet better.

October 1st.—Patient's conjunctivæ are becoming slightly jaundiced. He is more or less nauseated from time to time, and his appetite is poor. His bedsore is spreading rapidly and is almost impossible to keep clean. His urine is, however, much better, it contains less blood and is less foul; there is one and a half gramme of albumin to the litre.

October 5th.—Patient is failing rapidly; he is steadily emaciating; the nausea, vomiting, and anorexia continue. Urine and fæces still involuntary; the blood has nearly disappeared from the urine. Albumin, one-half gramme.

October 10th.—Patient is rapidly getting worse. The bedsore is very large, and is spreading in all directions. The sacrum is laid bare; and there is a deep gangrenous ulcer over each gluteus maximus as large as the palm of the hand; on the right side this gangrene extends outside the great trochanter, about two inches wide and five inches long down the leg; in depth it reaches almost to the femur. There is also a gangrenous spot over the internal malleolus of the left foot, about the size of a quarter of a dollar. The gangrenous areas are dressed twice a day. He is unable to move his toes now, but instead, there is rigidity of both legs, with extension of both feet. Turning him over to wash his gangrenous spots causes pain in both legs.

October 12th.—His temperature, respiration, and pulse, are and have been normal. His nausea and vomiting have ceased, but the anorexia continues. He is very weak, but his mental condition remains good. A gangrenous area has formed on the posterior aspect of the left calf, about two inches long by an inch wide. Nearly all of his buttocks are involved in the gangrenous slough, which is very offensive.

October 14th.—At 10 A.M. patient quietly died.

Autopsy (held less than an hour after death).—Body considerably emaciated; muscles of the legs very flabby. The gangrenous areas have been described. The brain and cerebral meninges were normal. The chest and abdomen were not opened.

Examination of the Cord Macroscopically.—The spinal meninges and the uncut surface of the cord looked normal. No extravasations of blood were to be seen. The amount of spinal fluid was normal. The cord was hardened in Müller's fluid. On cutting sections of the cord, all parts of it were found to have undergone pathological changes. In the cervical region there is well-marked ascending degeneration of the columns of Goll and the direct cerebellar tracts. These can be traced up into the medulla, where they gradually become lost. In the lumbar region there is descending degeneration of the pyramidal tracts, which gradually became smaller till they too disappeared at about the level of the first sacral nerve. In the dorsal region there appears to be a disseminated myelitis, its portion of maximum intensity being a space of about two inches long in the middle of the dorsal region. It gradually decreases in intensity on both sides from this maximum portion. Beginning from below upward, at about the level of the twelfth dorsal nerve, there begin to appear a few small yellow spots in the posterior columns. At first they are small and scattered, but as one follows up the cord they become more numerous. The spots are long and all lie with the long axis anteroposterior. There is a marked difference in the color of the same spots at different levels when the sections are cut pretty close together. In general, the relative value of the color of the spots is about medium between the gray and the white, when stained by Müller's fluid, *i.e.*, bright yellow and dark brown. But at some level, a small portion of the area, generally in the centre of the

spot, is bright yellow, and looks necrosed and somewhat crumbly. As we proceed up the cord the spots become larger and coalesce, until they occupy, at the region of greatest change, the whole of the posterior columns. Also, as we begin to go up from the twelfth dorsal, the degeneration of the pyramidal tract loses its distinctive character, and the degenerative area spreads and occupies nearly all of the posterior part of the lateral columns, and then spreads to a less degree and irregularly into the anterior-lateral columns. At the portion of maximum intensity a few small round isolated spots are seen in the anterior columns, the same bright spots being observed in the lateral and anterior columns as in the posterior. Above the portion of greatest change the pathological changes decrease rapidly, until only the ascending degenerations of the posterior columns and direct cerebellar tract remain. At first the degeneration on the posterior column is broad, but as it ascends it becomes narrower and more sharply defined, confining itself to the columns of Goll. The gray matter seems normal throughout. No evidence of hemorrhage can be found.

Examination Microscopically.—The gray matter appears normal everywhere. The large cells in the anterior horns are perfectly sharply defined, and the processes going from them are clear and distinct, as are also the nuclei. In the small spots of most marked change no axis cylinders can be found; extensive destruction of the fibres is present; in their place are large spaces, some empty, some occupied by degenerative products. The blood-vessels are enlarged and somewhat more numerous than normal, the adventitia is thick and studded with cells. No cells of Deiter's can be found. In the portions less acutely degenerated the same condition of affairs obtains, but to a less degree. The neuroglia is increased in thickness and is rich in cells; many alveoli are normal. Most of the nerve-fibres are enlarged and swollen; in many places the axis cylinders are very small, in others they have disappeared. Nowhere is there any trace of hemorrhage, nor of any infiltration of cells.

Summary of the Two Cases.—Case I., in which the disease ended in recovery; the patient came of healthy stock, was physically perfectly sound, had no alcoholic habit, and had never contracted venereal disease. The onset, occurring half an hour after his leaving the caisson, was sudden, without prodromata, and without pain in the legs or head, and with but a transient abdominal ache. The symptoms were of the nature of a complete paraplegia involving both lower extremities, bladder, and rectum. After the first week he began to improve and has steadily, though slowly, continued to do so. Motion was first obtained in his toes and gradually extended upward. At no time during recovery did he have pains in his legs, but he had some girdle sensation around the abdomen of no great severity. Ever since the accident he has had obstinate constipation. Control of his bladder was not regained until after four months: the bladder is still irritable and he cannot retain his water more than two hours. He was treated with electricity. His symptoms a year after the attack, when he first came under my observation, are those of a moderate spastic paralysis.

Case II., in which the disease ended in death, the patient came of a markedly consumptive family, had a strong alcoholic habit, and had contracted syphilis three years previously. The onset, occurring five minutes after his leaving the caisson, and preceded by the prodromata of giddiness, weakness, and nausea, was sudden, and without pain in head or legs. The symptoms were also of the nature of a complete paraplegia involving both lower extremities, bladder, and rectum. This patient steadily became worse and soon developed a gangrenous bedsore, which spread and deepened with great rapidity; he emaciated, failed, and died in about five weeks from the time of the accident.

At the autopsy, the contents of the cranium and spinal canal looked normal. The chest and abdomen were not examined. Later examination of the hardened cord showed, in the dorsal region, an area about two inches long, in which there were marked pathological changes in the white matter. The posterior columns and adjacent portion of the lateral columns were the parts most involved, though the diseased portion extended into the anterior part of the columns, though gradually shading off in intensity anteriorly. In this diseased portion there were irregularly-shaped spots of a different color from the rest of the cord, and at some level the centre of these spots seemed necrosed and somewhat crumbly. These spots were separated from each other by apparently normal tissue, but in the region of most change scarcely any normal tissue remained in the postero lateral columns. Above and below the diseased area were the usual ascending and descending degenerations.*

On microscopical examination there was extensive destruction of the nerve-tissue in the diseased portion, in places no axis cylinders could be found, their place being taken by spaces, some empty, some filled with degenerative products; other nerve-fibres were swollen; many axis cylinders were atrophied. The neuroglia was somewhat increased in thickness and was rich in cells. The advertitia of the blood-vessels was also increased in thickness. The gray matter was normal throughout.

The Published Necroscopies.—In order to give weight to any hypothesis, on anatomical grounds, that we may wish to advance, it is necessary that we should collect all the material possible that has been published on this subject, in order that by comparison of a great many autopsies we may be able to deduce conclusions as to the lesion or lesions regularly appearing in a preponderance of cases. To this end have been collected here all the reports of the necroscopies of persons dying from the caisson disease that have been found scattered about in a multitude of journals.

With the exception of two by Gallard, that I have been unable to obtain, this list is believed to be complete. Many other authors have observed cases of death from this cause, but they have failed to make, or at least to report, the autopsies. The published cases are very briefly as follows:

Case I. (Chabaud's,[17] No. 1).—L. C——, Italian, aged thirty three, locking out one minute (atmospheric pressure and length of time at work not stated). On emerging he had prostration, great dyspnœa and abdominal pain; his legs became paraplegic, and he had retention; a bedsore developed, and he lived one month.

Autopsy.—The blood was fluid and acid. There was a spot of softening in the gray matter of the cord, beginning at the level of the lumbar region of the cord, and extending upward 2½ ctm. The lower part of the dorsal region is of a rose color.

Case II. (Chabaud's, No. 2).—P. G——, aged twenty-three. Removal of pressure occupied one minute and a quarter. On emerging, great pain in the right thigh, which steadily became worse. Urine and fæces normal. Bedsore. Death after two months.

Autopsy (twenty-four hours after death).—Rigor mortis present. There was a large bedsore over the sacrum. The coxo-femoral articulation was opened, letting out a large amount of fetid pus. Anterior to the capsule is an opening into the abdominal cavity. There is a large abscess in the iliac fossa; the sheath of the psoas is full of pus; the lumbar plexus and obdurator are bathed in putrid pus. The liver is hard and congested; the spleen and kidneys normal. The bodies of the vertebræ are engorged with blood; the cord is hyperæmic, red, and arborescent. At lumbar enlargement there is a small spot that is more injected and a little yellow. The cauda equina is markedly congested. Head and thorax not opened.

Case III. (Heiberg's[52], [53] No. 1.)—*Autopsy:* Subject muscular, rigor mortis present. There are no signs of progressive putrefaction. On several parts of the

* See plates of sections of the cord taken from various levels, magnified six diameters, on page 144.

body, particularly on the lateral sides of the chest, and the hypogastric region, and on the internal and external sides of the left thigh are large livid spots; over these there is crepitation; there is also crepitation over the right arm and left knee where there is no discoloration. Pressure over the heart, when the sternum was raised, gives crepitation. Air is present in the great veins. The heart is hypertrophied; there are coagula and air in the ventricles. The lungs are congested. The spleen, liver,

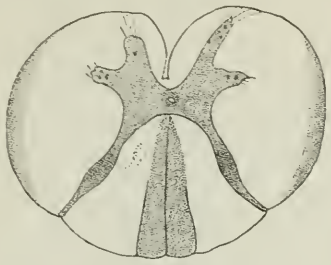

Fig. 1.—Second Cervical.

and kidneys are congested and contain air. The brain and membranes normal. The cord is soft; there is no congestion of the cord or membranes.

Case IV. (Heiberg's, No. 2).—F. K——, aged thirty. On coming out of the caisson he had pains in his legs, followed by paraplegia. There was paralysis of bladder

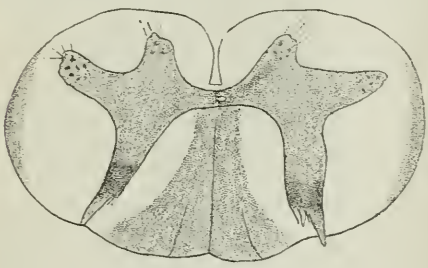

Fig. 2.—Eighth Cervical.

and rectum. He became semi-conscious and cyanosed, respiration stertorous, pulse small and rapid. In four days he died.

Autopsy.—There was bloody fluid in the bronchi. The lungs were congested. The cord softened, its margins sharply defined in the lower dorsal and upper lumbar regions. Nowhere is there exudation of blood and no inflammation. Everything else appears normal.

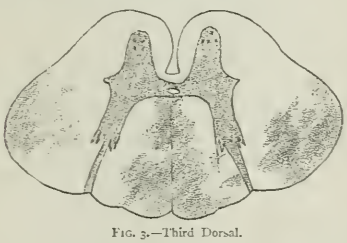

Fig. 3.—Third Dorsal.

Case V. (Gerard's [43]).—C. P——, aged twenty-nine. Worked a long time under a pressure of 2.10 atmospheres. Removal of pressure rapid. He went home feeling well. There he felt cold, had sudden anxiety, felt nauseated, fell unconscious, and died.

Autopsy (twelve and one-half hours after death).—Rigidity is intense. There was cyanosis of the head, neck, and abdomen; there was abnormal turgescence of the lateral sides of the neck. Gaseous crepitation very marked along the great vessels of the neck, also along the femoral and radial arteries Tympanitic resonance replaced the normal precordial dulness. The gas was discovered an hour after death.

Case VI. (Pol's,[46] No. 1).—The pressure was four atmospheres. Patient came from caisson and washed, then fell down, and died in fifteen minutes.

Autopsy (nine hours after death).—The meninges were injected, the sinuses engorged with dark blood. The

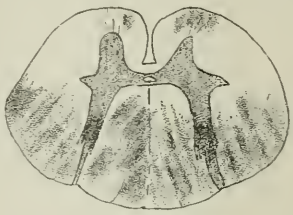

Fig. 4.—Seventh Dorsal.

spinal canal was not opened. The lungs were engorged, especially at the base. The bronchi were filled with bloody mucus The heart was normal; the stomach hyperæmic; the spleen, pancreas, and kidney congested; the intestines normal.

Case VII. (Pol's, No. 2).—Patient was a drinker. Locking-out occupied twenty minutes. Soon after leaving he fell, and died immediately.

Autopsy (thirty-six hours after death).—The face and lips were livid. There was general subcutaneous emphy-

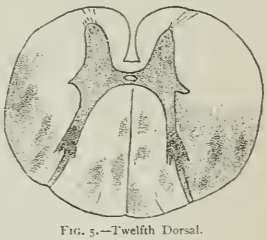

Fig. 5.—Twelfth Dorsal.

sema. Nothing abnormal was found in the meninges or brain. The cord was not examined. There was marked congestion of the lungs; the bronchi were hyperæmic and contained bloody serum. There was dilatation of the left ventricle. The right heart and vessels were gorged with blood. There were spots of congestion in the stomach. The spleen was large and congested, as were also the kidneys and pancreas.

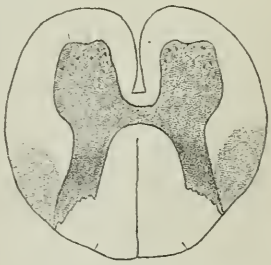

Fig. 6.—Third Lumbar.

Case VIII. (Granjon's [47]).—An Italian, aged thirty-three, worked six hours under a pressure of two atmospheres. On coming out he had pains in his legs, prostration, dyspnœa, and râles in his chest. Then he developed paraplegia of his legs, and retention. Bed-sores developed, and he steadily became worse, dying after five weeks.

Autopsy.—Diffluent black blood was found in all the organs. There was no meningitis. There was softening of the gray substance of the cord in the upper lumbar region for a distance of about two centimetres. At the centre of the infected portion was a spot, the size of a millet-seed, completely necrosed.

Case IX. (Clark's,[78] No. 1).—A German, aged thirty, worked two hours. Directly on coming out he had pain in the lower extremities, followed by paraplegia of the legs, and retention. After two weeks he died.

Autopsy.—The brain was softened. Pus was found below the arachnoid, covering almost all the brain; the pia and dura were adherent. There was an exudation between the dura and cranium. The dura of the cord was thick and opaque, and contained a serous pus. The substance of the cord was softened almost to a pulp as high as the fifth cervical nerve. The bladder was thick and soft, and saturated with extravasated blood; the mucous membrane was partly denuded and gangrenous. There was peritonitis, inflammation of the intestines, and gangrene of the rectum. The kidneys were large and contained several small abscesses in the cortex. The spleen was three times its normal size; the liver was congested and large. The lungs somewhat congested.

Case X. (Clark's, No. 2).—Patient aged twenty-two. On coming out he had pains in his legs and shoulders, in a few hours paraplegia of the legs developed, and there was retention. In twelve days he died.

Autopsy.—The brain and cord were congested. The latter in many places was pulpy. Serum was increased in the spinal canal. There were small drops of extravasated blood on different parts of the external surface of the dura. All the abdominal viscera were congested, the lungs less so than the other organs. There were extravasations of blood in both kidneys. The mucous membrane of the bladder was thick and ecchymotic.

Case XI. (Clark's, No. 3).—Patient aged thirty-five. Worked two hours. On coming out had paraplegia of both upper and lower extremities without pain. In a few hours he recovered the use of his arms and could move his legs slightly. After five days he died.

Autopsy.—The brain, cord, and meninges were highly congested. There was marked subarachnoid effusion. The cord was slightly soft in the lower dorsal region. The veins here were thrombosed. There were small clots on the external surface of the dura in the cervical and dorsal regions. The thoracic and abdominal viscera were highly congested. There were clots in the left kidney.

Case XII. (Clark's, No. 4).—Patient aged thirty-two. After coming out, pain developed in the arms and shoulders and lower extremities. After several hours, paraplegia of the lower extremities developed, and pain became less. There was retention of urine and constipation. Five days later he died.

Autopsy.—The brain was anæmic, the cerebellum pulpy.

Case XIII. (Clark's, No. 5).—On coming out he became unconscious. He developed a muttering delirium, but no paralysis. He died the next day.

Autopsy. — Brain, cord, and membrane congested. There was effusion of serum under both arachnoid and dura. The abdominal viscera were highly congested. The lungs were normal. The pericardium contained much fluid. There were small clots on the external surface of the dura mater of the cord.

Case XIV. (Clark's, No. 6).—Patient aged twenty-two. Worked two hours. After coming out he complained of great pain in both upper and lower extremities. This was followed by paralysis of both legs, bladder, and rectum. Nearly pure blood was drawn from the bladder. After four weeks he died.

Autopsy.—The brain and meninges were highly congested. There was an increased amount of serum in the spinal canal. There were clots on the external surface of the cord. The cord was soft in the lower dorsal region. The lungs were normal; the abdominal viscera were congested. The mucous membrane of the bladder was thick and ulcerated, one ulcer had perforated, setting up purulent peritonitis. The colon and rectum were gangrenous. The kidneys were intensely congested and contained blood clots.

Case XV. (Smith's,[107, 104] No. 1).—Englishman, aged thirty-eight. Corpulent. First day, worked two watches; pressure, thirty-five pounds. Immediately after coming up, had pain in the stomach and vomiting. In a few minutes pain in the legs, followed by paraplegia. On the following day he died.

Autopsy.—Showed slight engorgement of the lungs; brain, thoracic, and abdominal viscera normal. Spinal cord intensely congested; opposite the two lower dorsal vertebræ there was an extensive effusion of blood pressing on the cord.

Case XVI. (Smith's, No. 2).—Irishman, aged fifty. Worked half an hour more than usual, pressure being thirty-four pounds. Before leaving the lock he was found unconscious. Convulsions set in, and he died nine hours after the attack.

Autopsy.—Showed all organs healthy except the kidneys, which are the seat of marked Bright's disease.

Case XVII. (Smith's, No. 3).—A German, aged forty. Stout, heavy build. It was his first day at work. He worked two and a half hours, the pressure being thirty-four pounds. One hour after coming up, he first complained of not feeling well. He ascended the stairs of his house, sank down insensible, and died.

Autopsy.—Brain, heart, kidneys, larynx, normal. The lungs were remarkably congested. The spinal canal was not opened.

Case XVIII. (Jaminet's,[60] No. 1).—An Irishman, aged thirty-five. He worked once in the caisson for two hours. Died after nine days' sickness.

Autopsy.—The spinal cord was first opened; in dissecting down in the dorsal muscles, the veins were found to be very numerous, and distended with dark and tarry blood. The vascularity signally increased with the approach to the spine. The dura mater was very vascular; the canal contained a large amount of serum. Near the cauda, a moderately sized vein was completely thrombosed. The arachnoid of cord and brain was intensely vascular. Their structure succulent. The right heart was filled with coagulated fibrin. Posteriorly the lungs were the seat of hypostatic congestion. The kidneys were congested and contained hemorrhages. About the bladder was extravasated blood without any mechanical lesion. Intestines, liver, and spleen were hypostatically congested, with extravasation of blood.

Case XIX. (Jaminet's, No. 2).—A German, aged twenty-two. Worked for the first time, for two hours. Died in thirteen days.

Autopsy.—The brain and spinal cord were highly congested, the latter being softened in many places to a pulpy consistency. More than a normal amount of fluid in the canal. Small clots of extravasated blood on the dura. All the abdominal viscera were surcharged with blood, the lungs suffering less in this respect than any of the other organs. There were clots of blood found in both kidneys.

Case XX. (Jaminet's, No. 3).—A German, aged twenty-seven. Died the following day.

Autopsy.—The whole contents of the cranium were found highly congested. Blood oozed freely from the substance of the brain on section. The spinal cord showed conditions similar to those of the brain, with the addition of clots of extravasated blood on different parts of the dura. There were congestions of the thoracic and abdominal viscera, with extravasation of blood in the kidneys.

Case XXI. (Jaminet's, No. 4).—A German, aged twenty-one. Died on the next day.

Autopsy.—The contents of the cranium and substance of the brain were found overcharged with blood. The same condition existed in the spinal canal. All the

thoracic and abdominal viscera were intensely congested, clots of extravasated blood were found in the kidneys.

Case XXII. (Jaminet's, No. 5).—American, aged twenty-two. Died on the eleventh day.

Autopsy.—The brain and spinal cord, and its meninges, were found congested. The intestines and peritoneum were highly inflamed.

Case XXIII. (Jaminet's, No. 6).—Native of Denmark, aged twenty-eight. Worked for the first time a two-hours shift under a pressure of forty pounds. Taken sick at once. Paralysis of both legs and left arm and bladder. Lived four weeks.

Autopsy.—Pia of brain congested; increased amount of serum in ventricles. Spinal column not opened. The right ventricle contained a large clot; liver nutmeg color. Spleen very large. Kidneys large, and contained gangrenous patches.

Case XXIV. (Jaminet's, No. 7).—A German, aged thirty. Worked one hour at a pressure of forty-nine pounds. Taken sick at once on coming out, became insensible, and died in two hours.

Autopsy.—Brain and membranes congested. The spinal canal was not opened. The other organs were normal.

Case XXV. (Cotsonopoulos's[25]).—A. N— , Greek, aged thirty. Sponge diver. He had been diving for sponges, at a depth of one hundred and fifty feet. Immediately after rising he experienced great pain and heaviness in his legs, developing in an hour to complete paraplegia of the lower extremities, and also paralysis of the bladder and rectum. He developed cystitis and a bedsore, and died on the fortieth day.

Autopsy.—The veins in the spinal canal were markedly congested, with some extravasation of blood. On section, the lumbar and upper dorsal regions were soft.

Summary of the Autopsies.—Seven of the cases (Nos. III., V., VI., VII., XVI., XVII., and XXIV.) might be termed *foudroyant*, death occurring in from fifteen minutes to nine hours. The spinal cord was found softened in the one case in which it was examined. In five cases the brain was examined; it was congested in two, normal in three. The kidneys, spleen, liver, and lungs were congested in three cases, normal in two. In two of the cases, air was observed in the veins. One had marked Bright's disease. One was a drinker, the habits of the others not being stated. The average age of the men was thirty-eight years. The pressure under which they worked varied from two to four atmospheres.

Six cases were *acute* (Nos. IV., XI., XII., XV., XX., and XXI.), death occurring within a week. The spinal cord was congested or soft in all. The brain and all the internal organs congested in five. The average age of the men was twenty-eight years, nearly ten years younger than the first set. In three of the cases there was serous effusion in the spinal canal, and in four extravasations of blood on the dura of the cord.

In the subacute cases (Nos. IX., XVIII., XIX., and XXVI.), in which the men died between the first and second week, the spinal cord was found congested in all the cases, and the brain was congested in the three cases in which it was examined. Effusion of serum in the spinal canal was present twice. Cystitis and pyelitis occurred in two cases. The average age of the men was twenty-five.

The more chronic cases, those in which death took place between three weeks and three months (Nos. I., II., VIII., XIV., XXIII., XXV., and XXVII.), exhibited similar lesions to the preceding cases, *i.e.*, the cord was either congested or softened, the softening appearing usually in the lower dorsal or upper lumbar region, the abdominal organs were for the most part congested. Pyelitis, cystitis, and bedsores were the usual complications. The average age of these patients was twenty-eight.

From these, in many respects defective autopsies, it appears that the microscopic lesions consist in congestion or softening of the spinal cord (in all the cases in which it was examined); congestion of the brain (in 13 cases out of 16); and congestion of most of the internal organs (in 17 cases out of 22).

The Microscopic Examination of the Cords.—Important as is the information obtained from the macroscopic examination of the diseased organs, it cannot be compared in accuracy nor in fruitfulness to that derived from a careful microscopic examination of the diseased tissues, and it is to the absence of such careful microscopic examination that our ignorance in regard to the pathology of caisson disease is due. Strangely enough, previous to the case which I have examined and which forms the basis of this paper, in two cases only of this disease had the spinal cord ever been subjected to a microscopic examination. The great importance of these cases in any discussion on the pathology of caisson disease, and the fact that they are published in a foreign language, warrants me in introducing a brief report of them here.

Case XXVI. (Leyden's [67]).—The patient, K——, aged twenty, on July 26, 1879, had been working under a pressure of three atmospheres. He felt well until half an hour had elapsed after coming out of the caisson; then he experienced a feeling of pressure in the heart region, together with some dyspnœa. He fell to the ground and was unable to move his legs. His belly was much retracted. Retention of urine was at once developed.

August 1st.—The patient can slightly rotate the left leg, the reflexes are faintly present. His urine is bloody.

August 3d – His appetite is poor; he is emaciating rapidly, his pulse is small and rapid, and he feels weak. His urine is opaque, bloody, alkaline, and albuminous.

August 8th.—Death after fifteen days.

Autopsy (eleven hours after death).—The veins of the cord and meninges were congested. There was a considerable amount of clear fluid within the canal. On section of the cord the color was normal; the white substance projected in some places markedly on the cut surface. There were no evidences of hemorrhage to be found. The brain was normal, as were also the heart and lungs. The kidneys were large and hyperæmic; in the cortex were many small abscesses; in the pelvis there was a fluid holding pus; the bladder was thick and contained much pus and mucus.

Examination of the Cord Macroscopically.—The cervical and lumbar regions of the cord were normal. The dorsal regions presented a spotted appearance, the spots being of a yellowish color. The posterior columns and the posterior part of the lateral columns were the tracts most affected. The affected area of the cord occupied a space of about 10 ctm., its point of maximum intensity being in the middle, and gradually decreasing to the extremities. In the region of greatest change were found large sharply-bounded, irregularly oval areas. On cutting sections of the cord these spots were apt to fall out and crumble.

Examination Microscopically.—These long spots consisted of heaps of large round cells. In the posterior columns they seem to push aside the nerve-elements and lay in a slit; in these slits there was no nerve-tissue and no neuroglia, only the cells and small normal blood-vessels. There was no hemorrhage. The cells were round, the size of pus-cells, with nuclei, and mostly without fat. There was no pigment in the neighborhood of the cells. All about these spots the nerve-fibres were enlarged and swollen, and contained empty spaces. This appearance was, in some places, a small zone only around the area of cells; in other places it affected almost the whole of the posterior columns. The posterior part of the lateral columns had much the same appearance. The anterior part of the lateral columns and the anterior columns were here and there affected. The lesion of the cord, except the spots of cells, was an intense, fresh parenchymatous myelitis.

Case XXVII. (Schultze's [96]).—The patient, a healthy Italian, aged eighteen, was accustomed to the work. One day, under a pressure of 1.8 atmosphere, he worked

eighteen hours. On this day he worked six hours under a pressure of three atmospheres. Soon after leaving the caisson he experienced pain in both ankles, in about twenty minutes there was complete paraplegia of the legs. This was accompanied by retention of urine and constipation. Sensibility was diminished as high as the navel. The neck and spinal columns were tender to the touch. Sensibility improved somewhat, but cystitis and pyelitis set in, and his paraplegia did not improve. At the end of two and a half months he died.

Autopsy.—The meninges of both brain and cord were normal, as was also the brain itself. Externally the cord looked normal. After being hardened in Müller's fluid it was cut.

Examination of the Cord Macroscopically.—The greatest change was found to be in the lower dorsal region; beginning about one inch above the commencement of the lumbar enlargement, and extending to the middle of the dorsal region. In the posterior and lateral columns were found irregular whitish spots. In several parts of the lateral columns the substance seemed friable. There spots of changed color were found, sometimes in the posterior columns alone, sometimes in one or other of the lateral columns, under many combinations and forms. The gray substance appeared normal. In general, macroscopically there seems to be a disseminated degeneration of the white columns, of the dorsal region of the cord. In the lumbar enlargement there is a typical degeneration of the pyramidal tracts, and above the lesion there is an ascending degeneration of the columns of Goll and the direct cerebellar tract.

Examination Microscopically.—The pia and arachnoid are normal. There is no infiltration of cells anywhere in the cord. In no part is there full destruction of all the nerve-substance. In a strict sense there is no transverse myelitis. In the intensely degenerated part there is no complete abolition of nerve-elements; one sees a mass of fibres of not clear contours, somewhat transparent, and some closely packed cells the size of pus-cells, containing one or more nuclei. The blood-vessels, especially in the periphery of the lateral columns and in the areas of secondary degeneration, are markedly thickened, with the adventitia rich with cells. The gray substance in the cervical and lumbar region is normal; in the dorsal, on one side, in quite a circumscribed part there is degeneration. On the border of the posterior and anterior horns, at the height of the white commissure, there is a circumscribed spot that consists of felted glia tissue. Around some large blood-vessels there are spots containing small cells with or without nuclei, looking like the granular disintegration of Lockhardt and Clark. From extravasation, blood-pigment, or hæmatin there is absolutely no sign.

Summary of the Microscopic Examinations of the Cord.—The microscopic lesions found in these two cases (with the exception, in Leyden's case, of the breaks in the continuity of tissue filled with nucleated cells and normal blood-vessels) are almost identical with those found in my case, and permit the conclusion that most, if not all, cases of caisson disease are due to lesion of the cord, which attains its greatest intensity in the lower dorsal region, and which attacks the white matter rather than the gray, and which is of a degenerative nature, or due to a diffuse parenchymatous myelitis. The greatest amount of degeneration occurs in the posterior and adjacent portion of the lateral columns, diminishing anteriorly so that the anterior columns are but slightly affected; the gray matter being for the most part normal. Even in the most intensely degenerated portion there is no total destruction of all the nerve-substance. Above and below this area of disease in the lower dorsal region are, respectively, the usual ascending degenerations of the columns of Goll and the direct cerebellar tract, and descending degenerations of the pyramidal tract. In the substance of the cord no evidence of hemorrhage could be found.

Critical Discussion of the Theories.—The following theories as to the pathology of the caisson disease have been condensed as much as is consistent with clearness, but are sufficient as forming a basis on which we are enabled to discuss them intelligently.

All the theories naturally group themselves under three general heads, as follows,

I. The theory of exhaustion and cold.

II. The gaseous theory.

III. The theory of congestion with sequelæ.

The sequelæ under this last head are of five distinct kinds, and they appear during the period of removal of pressure. They are:

a. "Black blood." *i.e.*, blood deprived of its oxygen.

b. Evolution of gas in the blood-vessels.

c. Hemorrhage.

d. Acute revulsive anæmia.

e. Comparative stasis.

I. The Theory of Exhaustion and Cold.—This theory has for its exponents Bouhy, Barella, Lampadarios, Jaminet, and Woodward.

Bouhy,[10] and Triger,[11] in 1848, Barella,[2] in 1861, and Lampadarios,[61] thought that the pains produced were of a rheumatic nature due to the rapid chilling of the air on the workmen tired and bathed with sweat.

They however did not see the disease in all its intensity.

Jaminet,[60] in 1871, saw many serious and some fatal cases, and from his study of the disease draws these conclusions: "That exhaustion of the system under certain circumstances has been, with a very few exceptions, the cause of what has been called 'bridge cases.' As to the cause of the immediate paresis of paralysis happening on the men, they are not the result of inflammation of the brain or of the spinal cord, which could not yet have taken place, but exist only as a result of a too sudden or too strong reaction, succeeding to a general depression of the system, which is occasioned by too long a sojourn in a condensed atmosphere, and then paresis or paralysis is but the result of reflex action, caused by the spontaneous refrigeration of the whole system, but principally of all the abdominal organs."

Woodward,[115] as late as 1881, maintains that "The vital energies of the men taken sick were to a great extent paralyzed by loss of heat." This loss was due:

"1. To the expansion of the air in the lock while coming out.

"2. To the liberation of the gases held in solution, by the liquids of the body.

"3. To the expansion of the free gases and vapors in the body, when relieved of the abdominal pressure.

"4. To the severe physical strain of climbing the stairs."

This theory is insufficient to explain the phenomena observed. It must happen in this climate, every winter, that persons become more exposed to exhaustion and cold combined than do those working in the caisson. Yet such exposure does not produce such a complex of symptoms as is characteristic of the caisson disease.

II. The Gaseous Theory.—The theory of Bouchard[9] may be mentioned under this head. He states that gas is normally always present in the intestine. This gas becomes compressed by increased air-pressure, its volume being inversely as the intensity of the compression. That is, the volume of the abdomen will become four times less, if the pressure is four atmospheres, and the abdominal wall will be pressed against the vertebræ. Now, the abdominal wall is not an inert, but an elastic, partition, and tends by its tonicity and elasticity to expand. Bouchard maintains that in its expansion it reduces the pressure on the organs within it, and creates more or less of a vacuum; and so, acting as an enormous cupping-glass, it accumulates the blood from other parts of the body to itself, producing in them a profound anæmia, and in the abdominal organs a corresponding repletion. Then, at the moment of the withdrawal of pressure the intestinal gases resume their volume and distend the abdominal walls, and thus compress the various abdominal organs and blood-vessels, and push the blood stored up in them into the various other organs of the body, whose

vessels are deprived of their tonic elasticity by the variation of atmospheric pressure; and these latter, unable to resist the sudden irruption of blood, burst and produce the hemorrhages.

This theory of the action of the intestinal gases occupies a unique position, and is almost too whimsical to be discussed. Suffice it to say that, clinically, not a dozen of the several hundred cases that have been recorded have shown this symptom of abdominal distention. And besides, as external pressure increases, the gases in the stomach and intestines would assuredly seek their natural and easy exits; so that by the time atmospheric pressure became considerable, the intestine would be practically free from gas. Then again, hemorrhage is an infrequent complication, and not the real lesion.

The theory of the formation of gas in the blood has, in one form or another, numerous advocates. They are: Bert,[4, 5, 6] Boyle,[13] Cassait,[15] Catsaris,[16] Feltz,[37] François,[39] Gaveret,[42] Hoppe,[58] Leyden,[67] Leroy de Méricourt,[76] Musschenbroek,[80] and Rameaux.

Numerically this theory is the strongest; and fortified by numerous and convincing experiments, its upholders have presented their arguments with marked ability and great force.

As early as 1670, Robert Boyle, while experimenting with animals in the air-pump, ascertained that by rapidly exhausting the air in the air-chamber, bubbles of gas were found in the blood, and stated that animals in this condition died more rapidly than if they were simply deprived of oxygen. A century later, Musschenbroek, in 1755, confirmed these experiments on animals in a vacuum.

Hoppe, in 1847, still a hundred years later, made a series of experiments in the same direction, and states that death is caused by obstruction of the capillaries of the lungs by the bubbles of air, or by the arrest of circulation.

Of all the experimenters in this line, a Frenchman, Paul Bert, has been far more active and ingenious in his experimentation than any other, and has left behind him a large and valuable work on the subject. He agrees with his predecessors of the gaseous theory, that gas is set free, but says that it is not oxygen, but nitrogen returning again to the free condition that causes the mischief.

Bert's experiments,[4, 5, 6] which the members of the French school quote to substantiate their theory, are misleading, and cannot be applied to human beings. They were conducted on animals under a pressure of from six to nine atmospheres, the pressure being suddenly withdrawn. Below five atmospheres no symptoms were produced with rapid withdrawal of pressure, and if at five atmospheres three minutes were allowed for the removal of pressure, no air-bubbles formed in the vessels.

Now, in the United States at least, workmen have never been subjected to a pressure as high as five additional atmospheres, and the time of locking-out here occupies from three to eight minutes or more. Yet symptoms are frequent, and death has occurred after a pressure of two atmospheres.

According to Bert's experiments, then, no gas would have formed in these cases; and as a matter of fact no air has been found in the blood-vessels of any of the sixteen men who died from the caisson disease in this country, and on whom autopsies were made.

Catsaris,[16] a Greek professor of medicine at Athens, is the most recent author on the subject. He has just finished publishing an interesting series of articles on the symptoms as they appear among the divers for sponges near Greece.

He is an enthusiastic upholder of the theory of the formation of gas in the blood, and has made many experiments to prove his statement. He decries in toto the theory of congestions and their sequelæ. In this connection he says: "It is useless to remark that it is an erroneous doctrine." Again, he states that "physiology gives its death-blow to this theory. She teaches that barometric pressure has no direct influence on the liquids of the organism, and equilibrium of pressure exists throughout the entire mass of blood. The absolute incompressibility of our liquids gives then a refutation of that theory of the physical compression of the external tissues."

Catsaris has recognized that the experiments of Bert do not apply very well to the conditions under which workmen ordinarily work. Therefore, he has made some experiments with dogs, reproducing the same conditions under which men working in compressed air are subjected. He shut the dogs up in the divers' apparatus, and let them down in the sea to the same depth, and for the same time, and removed the pressure as rapidly as is customary among the workmen.

The following experiments are condensed from his reports:

1. A dog was immersed in twenty-eight fathoms for half an hour, removal of surplus air-pressure occupied forty seconds. On first emerging he was perfectly well. After thirteen minutes he began to stagger, and five minutes later his hind legs commenced to be paralyzed; which paralysis was complete on the following day. On the second day after the immersion, his symptoms remaining the same, he was killed. Advanced softening of the cord in the region of the lumbar enlargements was found. The lateral and posterior columns, especially on the right side, were colored a yellowish gray; a little below this region, transverse sections showed the gray matter to be red; the posterior horn on the left side a spotted red. Above this section the gray matter was uniformly red, but without softening of the white matter. The rest of the cord is firm. There is no congestion. By the aid of a magnifying-glass, one could see certain bubbles of gas in the middle of the soft portion. Air comes out of these vessels surrounding the necrotic part. Gas could not be found elsewhere.

2. This animal was kept an hour in a depth of twenty-five fathoms; withdrawal of pressure took fifty seconds. Thirteen minutes after coming out he commenced to drag the left leg; five minutes later it was completely paralyzed; sensibility was preserved on the paralyzed side, but was obtuse on the right side. There was no paralysis of the sphincters. Half an hour later he commenced to get back the use of his leg, and sensibility also returned; twenty minutes later he had completely recovered. He was then killed. On opening the ventricles a certain number of gas-bubbles came out of the left, much less from the right. Transverse section of the cord showed in the left half of the upper lumbar region, by the aid of the magnifying-glass, bubbles of gas obliterating the blood-vessels; one could find the bubbles in the tissue of the cord also, they were present to a very slight extent on the right side. In no other region of the spinal cord could they be seen.

3. This animal was immersed in twenty-three fathoms for an hour and a half. Removal of pressure one minute. Six and a half hours later, no accident following, the dog was killed, and by the aid of a lens small bubbles of gas could be found in many parts of the blood-vessels.

Thus, in these three cases, and in fact in all the cases in which he experimented and killed, the necroscopy showed bubbles of air in the vessels. Now, these bubbles, some of which could be seen with the naked eye and others by the aid of a magnifying glass, even after two days, must all of them have been of considerable size; that is, large enough to block the small arteries, as the capillaries are invisible even with the aid of a simple lens. They must have all been formed within one minute, the longest period recorded for the withdrawal of pressure, and they must have been formed suddenly all over the body. If they produced any effect at all, it must have come on at once, and circulation in the capillaries throughout the body must have suddenly ceased. In that case death should have been sudden. Nothing of the kind occurred. In one, death did not occur for two

days, another recovered in an hour, and the third suffered no symptoms; yet gas was found in all. If gas was found at the seat of lesion in the case that so rapidly recovered it must still have been blocking up the arteries, and the lesion still should have increased and have become worse. How then could this gas have been the eminent factor in the etiology? Why does this gas, that is produced all over the arterial system, confine its pathological effects to the lower part of the cord? One would expect the functions centring or passing through the medulla to be equally as markedly interfered with, but this is not the case. As the gas is formed everywhere, it must also form in the coronary arteries and interfere with the nourishment of the heart, and produce very marked irregularities of its action. Clinically we know that this does not happen.

The advocates of this theory have not attempted to explain why it wreaks its vengeance principally on the lower part of the cord.

Let us examine now a little more closely the quantity of gas dissolved in the blood. An experiment by Smith,[173] in this connection, is interesting and instructive. He says: "The pressure in the caisson being about thirty-five pounds, a dog was sent down, and allowed to remain seven hours in the compressed air. At the end of that time I went down and, after killing the animal with prussic acid, I opened the vessels of the neck and allowed four ounces of the fluid to flow into a six-ounce vial. The space above the blood was then completely filled with olive-oil, and a cork, pierced by one leg of a V-shaped tube, was forced tightly into the bottle, displacing a portion of the oil, which escaped through the tube. By this arrangement every particle of air was excluded from the apparatus, even the tube which extended a little below the cork being filled with oil. The object of the oil was to avoid the difficulty which would arise from coagulation of the blood in the tube if blood only were employed.

The apparatus was then taken into the open air. While passing through the lock five minims of oil escaped from the tube, which amount was increased during the next half-hour to eight minims. The temperature of the caisson and that of the external air were almost exactly alike, so that the result obtained could not be influenced by contraction or expansion due to temperature. The eight minims, therefore, represented the bulk of air which was disengaged from the blood in consequence of the removal of the excess of pressure."

Magnin,[71] Couty,[39] Petit,[84] Feltz,[37] Demarquay, and many others have shown that very large quantities of air can be slowly introduced into the veins without producing any effect. As high as 750 to 1,200 c.c. have been injected into the veins of medium-sized dogs without producing even syncope.

The advocates of the theory of formation of gas in the blood-vessels recognize this fact, and state that the amount of gas formed in the veins is immaterial; but that it is the gas in the arteries that causes the trouble.

Experiments on the introduction of air in the arteries are much less numerous than those of air in the veins. But Petit[84] says, "A very large amount of air injected into the aortic system produces syncope and convulsions, symptoms resulting from the stoppage of the blood-current."

From the experiment by Smith, just given, we see that the actual amount of gas stored up in the blood is very small. That is, in 120 c.c. of blood, there was only ½ c.c. of air developed, and this was, of course, not developed instantly; and it was formed in the veins as well as in the arteries; one-half only of this small quantity was present in the arterial system. It seems impossible that such a small proportion of air could produce so much mischief; especially when we consider the fact that gaseous emboli are not hard bodies becoming impacted in the vessels, but are soft and elastic, and must allow a considerable stream of blood to pass along their sides.

Catsaris and others of the gaseous theory recognize that length of sojourn under compression is an important etiological factor in producing the disease, but their reasoning from the fact is false. For instance, Catsaris exposed a number of dogs in the diving-suit at certain depths—eighteen to twenty-three fathoms—for from five to fifteen minutes, the withdrawal of pressure occupying one minute, it being the same in all cases. No accidents happened to the dogs in any of the tests. Then, employing the same dogs, he allowed them to remain under water from an hour to two hours and a half, the other conditions being the same. It was found in this series, that all the animals suffered from paralysis of the hind-legs, some speedily recovering and others dying. He reasons from this that the longer they remain under pressure, the more gas is dissolved, so that at the moment of removal of pressure more gas is suddenly set free, causing greater wreck. That cannot be so according to Dalton's law, which says, that with a given temperature "the weight of gas dissolved by a given volume of liquid is directly proportional to the pressure the free gas exerts on the liquid." Therefore, as soon as a liquid at a given temperature and pressure becomes saturated, length of time is no further factor. Now, as the blood circulates so rapidly in the vessels, it must have had abundant time to become saturated in its passage through the lungs before the expiration of the five to fifteen minutes occupied in the first set of experiments; and besides, we must add a minute or two to each of the above experiments during which the animals were descending to the depth of from one hundred and ten to one hundred and forty feet, and during which time, of course, the pressure was steadily increasing.

Smith proved that blood will part with five-eighths of its surplus air during the period of withdrawal of pressure, and of course it will absorb it as rapidly during the increased pressure, or even more so, because normally the blood is in rapid circulation, while in his experiment the blood had been withdrawn from the body. The blood, then, in Catsaris's first series of experiments being saturated, and producing no symptoms on rapid removal of pressure, we must look elsewhere for an explanation of the morbid phenomena produced by the long sojourn under pressure. This will be given when we come to study the effects of congestion. If Dalton's law is true, which I think no one doubts, it must apply equally as well to birds and amphibious animals as to mammals.

Now, let us see what experimenters have found. Hoppe[58] made experiments both in mammals and in amphibious animals; and found that while mammals rapidly succumbed after rapid removal of a certain pressure, yet amphibious animals did not; and that it took a much higher pressure to produce given effects in them than it did in the warm blooded animals. The only explanation he could give that the amphibious animals did not follow Dalton's law was, that they are cold-blooded. This reasoning is weak, but let us accept it a moment. We know that the birds are warmer-blooded than mammals, and so using Hoppe's argument that the warmer the blood the more rapidly is the animal affected, the former should be affected quicker by pressure than the latter. What, however, is the fact? Burt experimented on birds as well as animals, and was surprised to find that while mammals began to show effects at six atmospheres, and nearly all at eight, and that none could withstand nine atmospheres, yet birds could withstand ten, and it took a long time, even at a pressure as high as fourteen atmospheres, to subdue them.

Classes of animals like birds and amphibious animals, though they are widely separated as regards blood-temperature, are yet accustomed by their manner of life to sudden variations of pressure; and so, as might be expected, are but little or not at all affected by sudden artificial change of atmospheric pressure, which animals living continuously under the same pressure are unable to withstand. And even among individuals of the same class, for instance among men, clinical experience has

shown that individuals show marked difference in their ability to withstand the same pressure.

Now, the theory of the formation of gas in the blood being a mechanical one, following the law of Dalton, all vertebrates should suffer equally at given pressures under like conditions. This has just been proved not to be the case, so we have a right to deduce (1) that the temperature of the blood has nothing to do with the ability of an animal to withstand high pressures; (2) that the theory of the formation of gas in the blood is insufficient to be the sole, or even the main cause for the pathological effects produced.

(To be continued.)

CRYSTALLINE FORMS OCCURRING IN KOCH'S TUBERCULIN.

By JOHN C. HEMMETER, M.D., PHIL.D.,

BALTIMORE, MD.

THE subject of the animal alkaloids produced by pathogenic bacteria in different forms of disease is one of great importance. This is particularly true of the products of the bacillus of tuberculosis; a large field is open to investigators in this direction. Failure on the part of most previous investigators to find a chemical poison in pure cultures of tubercle bacilli may, as S. Martin[1] has pointed out, be due to the fact that they employed substances like beef-tea, glycerine, glycerine agar-agar, and glycerine broth, which are not met with in the animal body. Martin has shown that glycerine is not necessary at all, and an exuberant cultivation could be obtained if alkali albumin is used with an amount of salts added in proportion to those of serum. It seems unnecessary to use any other products than those found in the body, and alkali albumin is the nearest approach to a natural medium that can be sterilized and handled with convenience.

Koch has not informed us what culture-medium he uses in the preparation of tuberculin, but it is probable that it resembles that suggested by S. Martin in composition. Dr. A. Libbertz informs us that blood-serum, which was stated to be the medium used in the preparation of tuberculin, is not employed by Koch. Concerning the manner in which tuberculin is made, we know nothing more to-day than at the time of Koch's publication concerning its composition. We are told that it is derived from a pure culture of tubercle bacilli, by extracting it with a fifty per cent. solution of glycerine; that it contains a certain quantity of mineral salts, coloring substances, and other unknown extractive matters. That the effective substance in tuberculin is insoluble in absolute alcohol, by which it can be precipitated, though not, indeed, in a pure condition, but still combined with the other extractive matter. Regarding the constitution of the more effective substances, Koch gives us no exact information. He supposes them to have a close affinity to the albuminous bodies, but that they do not belong to the group of so-called toxalbumins, because they bear high temperatures and in the dialyzer go easily and quickly through the membrane. The proportion of the effective substance in the extract is estimated at fractions of one per cent.

The fact that the exact composition of the culture-medium is not given is unsatisfactory. But from the fact that in the statement of the composition of the lymph "a certain quantity of mineral salts" is referred to, we infer that these salts were originally contained in the culture-medium to which they were added to approach the composition of serum. These salts could be derived only from two sources, either from the culture-medium or from the bacilli themselves; no other factors enter into the composition of a pure culture. At the clinic of Nothnagel a most careful investigation of the chemical composition of the tubercle bacillus has been carried out by Dr. Hammerschlag, who had begun his studies on the bacillus at Professor Nencki's chemical laboratory at Berne. It is not feasible for us to enter into the methods and complete results of this analytical study: what concerns us here is that mineral salts are not mentioned as constituting a part of the bacilli. If such salts occur in tuberculin they are therefore derived from the culture-medium, not from the bacilli; nor can they be a product of the activity of the bacilli in the medium.

In attempts to separate out crystalline bodies from organic mixtures, such as glycerine extracts of bacterial cultures,[1] the probability of recrystallization of the salts occurring in the culture-medium must be borne in mind.

The crystalline forms of all salts that could possibly occur or be used in the ordinary culture-media, we must be familiar with, lest such bodies be mistaken for an alkaloid of bacterial origin. To eliminate blood-serum as one of the possible culture-media used in the preparation of tuberculin, Mr. Theodore Hough and myself had, before Libbertz's letter was received, made spectroscopic studies of tuberculin in the biological laboratory of the Johns Hopkins University, with a view to recognizing in the spectrum the absorption bands of oxyo or reduced hæmoglobin, or of hæmatin (alkaline); but our results were negative.

The literature on the chemical composition of tuberculin is limited; we are familiar with two analyses. One by Schnitzler, of Vienna (London *Lancet*, December, 1890), who concludes that besides peptones the main active substances in it are protein bodies allied to toxalbumins. His analysis was made during a period when tuberculin was a rare thing, and he could not obtain enough of it to shake the liquid with ether and alcohol to separate the alkaloids, if present, from the albuminoids. Schnitzler asserts, however, that acid bichromate of potassium, which reveals the presence of alkaloids and ptomaïnes even when mixed with albuminoids, failed to give any reaction, so that the absence of alkaloids and ptomaïnes were taken for granted.

The second analysis which has come to our notice is not one of tuberculin, it is true, but of prepared liquid cultures of tubercle bacilli.[2] Crookshank found, according to the stage of the cultivation, a complex proteid substance, or this substance with free ptomaïne, or ptomaïne alone, and concludes that the tubercle bacillus produces a complex proteid poison, in which, as in anthrax, the alkaloid of tubercle exists in a nascent condition. Dr. Sidney Martin, who has given us many valuable contributions concerning the toxic products of the bacillus anthracis, was not convinced that the reactions of Professor Crookshank proved that an alkaloid was present in pure cultures of tubercle bacilli.

About the end of February, 1891, I discovered definite crystalline forms in a specimen of tuberculin which had been received from Dr. A. Libbertz, of Berlin, and which had been allowed to evaporate over concentrated sulphuric acid for two months. This process of evaporation might be accelerated if it is allowed to go on in a vacuum. In one specimen of tuberculin the crystals were obtained after simple evaporation, without employing the sulphuric acid. After studying the crystalline forms of all salts that might possibly be employed in culture-media, or occur as a constituent of such, I concluded that the crystals were not derived from the medium that had been used. Dr. A. Libbertz, with whom I communicated concerning these crystals, confirmed their existence in tuberculin, but admitted in his reply that their nature and composition were perfectly unknown to him; which strengthened my view that they could not be derived from the culture-medium, nor had been added, as some supposed, to preserve the solution. More light concerning their real nature was obtained when we injected diluted solutions of

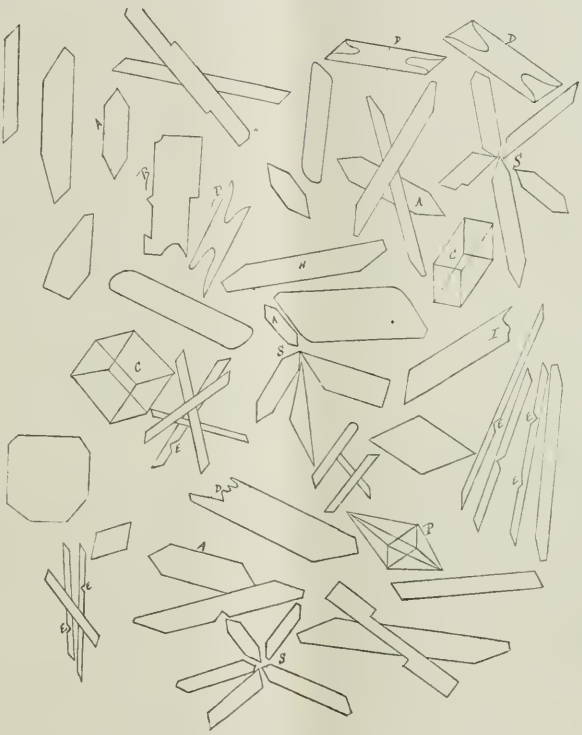
these crystals into guinea-pigs, and subjected them to various chemical tests.

These crystals can be obtained from tuberculin: 1. By simple prolonged evaporation in sunlight under aseptic precautions. 2. By evaporation over concentrated sulphuric acid, if possible in vacuo. 3. By dialysis, using distilled water slightly acidulated with sulphuric acid; after eight days' dialyzing, evaporating, and recrystallzing, owing to the large amount of water which is necessary in this method, only traces of crystals could be found, even after evaporation. 4. By the Stas-Otto process of separating alkaloids.[1]

The crystals which I have found in Koch's tuberculin are colorless, and, as shown in the accompanying cut, vary much in size, configurations, and dimensions. The figures of the crystals accompanying this report are not drawn to scale. The crystals like those marked *A* in the drawing have been found to vary in length from .00375 to .0225 micromillimetres, and from .0026 to .01125 micromillimetres in breadth. Crystals having the shape of an oblique parallelogram, like the one marked *H* in the drawing, with the two acute angles at opposite ends of the longest axis bluntly cut off, simulating very much certain crystalline forms of inosite, vary in length from .044 to .01875 micromillimetres; and from .0075 to .01125 micromillimetres in breadth. The forms marked *D* in the diagram are not perfect crystals, but owe their peculiar shape to the disintegrating action of the solvent in which they were mounted, generally a saturated solution of glycerine. When observed on a glass-slide, in a drop of an evaporated specimen of tuberculin, the crystals exhibit a tendency to stellate or rosette grouping, *i.e.*, several crystals will be arranged so that their long axes are directed to one point like radii; this is shown at *S* in the diagram. The form *P* in the diagram was observed but once, and then the specimen was imperfect; it simulated an imperfect monoclinic pyramid, but the apex of one side was dissolved away and was added in the drawing; broken forms of this type, which is extremely small (.00375 m m. longest axis), were occasionally seen. Some of these broken pyramids were so small that it was impossible for us to recognize whether their bases were hexagonal or quadrangular. The forms marked *C* in the diagram are not perfect cubes, but their axes have one oblique intersection. By far the largest number of forms, if not all, belong to the monoclinic system of crystallization. The notches which appear punched out of the sides of the long slender crystals at *E*, are the results of mechanical compression of one crystal upon another. The odd form *B* is due partly to action of the solvent, partly to compression. These crystals are not present in all specimens of tuberculin in the same proportion. In one specimen, consisting of five grammes of tuberculin, 0.0059 grammes of crystalline structures were separable as hydrochlorides; from a second specimen 0.004 grammes were separated by the Stas-Otto method. The crystals, as such, when separated out simply by evaporation, are insoluble in water, but are soluble in dilute acid, forming a compound with the acid used, and can be reprecipitated by ammonia. Whether these crystals represent one or more chemical bodies, and what their chemical constitution is, are questions which at present we feel ourselves unable to grapple with. As already stated, some of the forms closely simulate crystals of inosite, which also crystallizes in large colorless monoclinic prisms, but in the crystals separable from tuberculin there are forms widely differing from those of inosite. We could only understand the occurrence of inosite in the tuberculin if meat-juice (bouillon) had been used as a culture-medium.



The crystals found by us have some of the properties of alkaloids. They are, in the first place, alkaline, insoluble in alcohol and water, soluble in dilute acids. Potassic or mercuric iodide produces a dirty, whitish precipitate, soluble in excess of reagent. Sodium phospho-molybdate causes a yellowish precipitate in solutions to which nitric acid in very small quantities has been added. The reactions with chloride of gold and platinic chloride were not convincing. The preparation of these crystals from tuberculin is too expensive a method as yet to encourage an exhausting chemical study. The crystals, when injected into the circulation of guinea-pigs, prove very poisonous. From five grammes of tuberculin 0.0062 gramme of the crystals had been obtained; they were converted in a solution with a drop of hydrochloric acid and five grammes of distilled water. We had thus restored the original bulk of the solution. Two centigrammes of this solution injected subcutaneously into guinea-pigs caused clonic spasms of the muscles, accelerated breathing, in one hour general convulsions, and death following in from six to twelve hours. Further aims in investigating this substance will be to determine, by preparing larger quantities, whether it is an alkaloid. If so, whether it can be separated from tuberculous tissues (lungs, glands, etc.). The physiological effects of solutions of these crystals in first, normal, second, tuberculous animals. These means may enable us to judge whether we are here dealing with a tuberculo toxine.

In No. 22, vol. xvi., of the *Journal of the American Medical Association* (May 30, p. 788) Dr. Joseph Jones, of New Orleans, La., has contributed an article entitled "Observations on Koch's Lymph." Dr. Joseph Jones

[1] As modified by Stevenson, Watt's Dictionary, vol. i., 1883, art. Alkaloids, Poisonous.

states that he has found in tuberculin organisms which resembled and reacted to staining reagents like tubercle bacilli. He observed that the addition of a drop of the lymph to Pasteur's fluid was followed by the development of spores and slender, rod-shaped organisms resembling the bacillus of tuberculosis. Dr. J. Jones asserts that he has cultivated the spores and bacilli of Koch's lymph, with the necessary precautions to exclude external organisms, on various substances and culture-media. A small quantity of the lymph was added to a carefully sterilized solution of crystallizable sugar, and the clear solution became turbid from the development of bacilli.

These observations of Dr. J. Jones, if accurate, would be of ominous importance, and I made special efforts to detect these spores and tubercle bacilli in tuberculin while studying out the nature of the crystals just described. One hundred and twenty-four slides were studied, with a movable stage, Vernier scale, and micrometer —no organisms or spores were detected. It should be stated that special efforts were made to examine the sediment from the bottom of vessels that had stood undisturbed for months. I am able to confirm Dr. Karl von Ruck's observation, that five per cent. solutions of tuberculin will keep perfectly clear of bacterial developments for three weeks without especial aseptic precautions. Tuberculin inoculated into Pasteur's fluid sterilized caused no bacterial formations in my experience, and these experiments were done in my office, where aseptic methods are by no means as complete as in the laboratory.

I am indebted to Dr. Alfred Dohme, of this city, for his valuable assistance in determining the weight and quantities of the crystalline bodies before described.

THE PRIMARY CAUSE OF DEATH FOLLOWING BURNS OF THE SKIN, WITH THERAPEUTIC OBSERVATIONS.[1]

By S. LUSTGARTEN, M.D.,

NEW YORK.

THE desire to solve the mystery which surrounds the primary cause of death in consequence of burns has brought forward a great number of theories. Some of these theories have been absolutely refuted. Among these are that of the congestion of internal organs, the suppression of skin respiration, ammoniæmia, the thickening of the blood, cooling, and the diminution of the activity of the heart. Other hypotheses, such, for example, as that of the destruction of the blood corpuscles, with possibly a simultaneous uræmic intoxication, find no clinical or anatomical support, and the same may be said of the theory of shock, the reflex lowering of the vascular tone, and that advanced by Sonnenburg, viz., the over-heating of the blood and the consequent paralysis of the heart.

It is not my intention to consider all the theories critically and in detail, the more as this has been recently done in a paper by Welti,[2] and in another by Silbermann.[3] The purpose of this paper is rather to present views differing from those named, which have forced themselves upon me, and which are supported by clinical observation and by a number, though small, of experimental and therapeutic results.

I was unfortunately prevented for a long time from continuing the investigations which I had begun with reference to this subject by circumstances connected with my coming to New York. The views to be advanced later, as far as they stand the test of scientific criticism and find confirmation, have, however, practical consequences, and this leads me to delay no longer with my publication. I have not been able to free myself from the idea that an intoxication lies at the bottom of the fatal symptoms following burns of the cutaneous surface.

Let us look briefly at the symptoms observed in these cases, considering only the typical and essential, and neglecting the rare complications, such as aneuria, nephritis, and ulceration of the duodenum. When the patient recovers from the immediate impression of fear of the flame or the heat he appears calm. Pulse and respiration are nearly normal, he answers promptly and clearly the questions asked, and describes his accident. The consciousness of a danger passed, as he believes at least, produces a feeling of well-being which is disturbed only by pain in the injured part. This relative euphoria lasts, according to the extent and severity of the injury, for hours, days, or in rare cases a fortnight. The picture then changes, and symptoms appear which, varying in the rapidity of their development, lead regularly to a lethal ending. (I know of but one exception to this course, and that I shall refer to later.) The patient then appears ill. From time to time he tosses about, his eyes do not seem to fix, his answers are slow, and his breathing is deep and sighing at times. This deep sighing is the first link in the chain of really ominous symptoms. Singultus soon appears, and following this, with the increasing restlessness of the patient comes vomiting, at intervals of several hours at first, and more frequently later. The temperature varies within some tenths (C.), the pupils are of average width or somewhat contracted, the respiration is rapid and superficial, and from time to time there is deep spasmodic inspiration. The general restlessness of the patient increases, he tosses from one side to the other regardless of the pain, and in a condition as of drunken excitement; he talks at random, cries out, clenches his fists, etc. The attempt to give him food gets to be more and more frequently followed by vomiting. When roused he is still able to answer the questions asked him, although slowly and only after deep thought; and he complains of a feeling of pressure in the region of the stomach. After a time the restlessness decreases, the muscles relax, the patient becomes drowsy so that he cannot be roused, and finally a sopor lasting an hour or more, interrupted by twitching, leads to a general paralysis.

If we suppose that shortly after the injury the absorption of an intoxicating substance begins and goes steadily on, the peculiar course of the symptoms is explained in a rational, unforced manner. First there is the free interval up to the appearance of the ominous symptoms, due to the fact that a certain time must elapse before the poisonous substance comes into action, and that a certain quantity of this substance must be formed in order to produce the objective symptoms. The length of this free interval stands in general in an inverse ratio to the intensity and extent of the injury. The symptoms which then come on are, first, those of irritation on the part of the vagus and the cerebral cortex, and these run their course, varying according to the extent of the burn. The stage of irritation is followed later, exactly as in the case of poisons like the alkaloids, by a state of paralysis, which finally closes the scene.

The idea of an intoxication has suggested itself to earlier observers,[1] but their theories, viz., the suppression of the perspiration of the skin, the poisoning by prussic acid, the ammoniæmia, and the auto-intoxication with fibrin ferment, have not gained general acceptance.

Whence, then, does this supposed poison come, and what is its nature? I should first remark that all my statements refer to burns which have caused death of the tissues—eschar. With this group I would include certain burns of the second degree, since experience has taught me that necrosis often occurs in such, although it is superficial beneath the bullæ which are formed. I exclude burns of the first degree altogether, since personally I have not seen death follow in such cases. But since such results are reported by accurate observers, I should

refer these rare cases, clinically different from the others, to other causes, such as shock, over-heating, or the lately-reintroduced idea of the alteration of constituents of the blood, and consecutive thrombus formation.[1]

My explanation supposes the formation of an eschar. Under the influence of the heat the skin loses its vitality. The temperature required for this is not necessarily a high one, since one of 60° to 70° C. is sufficient to destroy the vitality of living protoplasm. The temperature is generally higher than this, however, since unless its action were long continued the poor heat conduction of the horny layer would prevent injury to the deeper tissues. Under the influence of warmth the blood- and lymph-vessels dilate, and the skin becomes tense. With the requisite temperature there occurs coagulation of the blood, the lymph, and the protoplasm of the cells. We are not justified in supposing further chemical decomposition in a fresh so-called "white eschar." The eschar is closely connected with the surrounding unaffected tissues and cannot shrink, and if the temperature has not been so high or so long-continued as to cause charring, the eschar appears as a grayish-yellow insensitive mass, pervaded with brownish-red dendritic vessel-casts.

This dead mass now becomes in most cases the seat of decomposing processes. Micro-organisms of putrefaction, which, lying in the depths of the follicles, have escaped the action of the heat, or which have wandered in later, very soon begin their work; and, if the patient lives long enough, we see as the expression of this that the affected skin turns into a yellowish greasy pulp, swarming with micro-organisms, and is gradually cast off in shreddy layers. The conditions are especially favorable for the development of putrefaction. The dead mass lies in a thin layer on the surface, as in an incubator, and takes up water from the subjacent tissues by diffusion, and under these circumstances poisonous bases of putrefaction necessarily form. The conditions are most favorable, too, for the resorption of the bases, as long as the eschar does not fluidify under the influence of a peptonizing ferment, so that a portion of the poison is carried off in this manner.

What is the nature of these toxines? Analogy and the clinical aspect of the cases point unmistakably to a group to which belong neurin, muscarin, and the allied bases of similar action. These are derived from cholin, and Brieger, to whom we owe so much in this field, found them almost constantly in a number of putrefactive processes, as in decaying horse-flesh, fish, cheese, and in human cadavers. Their great virulency is indicated by the fact that 5 milligr. of muscarin cause severe symptoms of poisoning in man. It is further probable that the rich supply of oxygen to which the extensive superficial eschar is exposed, favors the development of a number of poisonous ptomaïnes. I conclude as much from the statement of Brieger, who in one experiment[2] was not able to isolate any poisonous matter from two hundred pounds of parts of cadavers which had been left to putrefy closely packed over each other; and he says: "The entrance of a certain amount of atmospheric oxygen seems to be necessary in order that the bacteria of putrefaction may produce virulent ptomaïnes."

The clinical picture sketched above also supports the idea of a poisoning with ptomaïnes similar to muscarin. Of the characteristic symptoms of the latter, we find present the irritation of the vagus, especially of the gastric plexus, the condition of excitement similar to drunkenness increasing often to raving, and possibly the spasm of accommodation. Wanting altogether, or exhibited in but slight degree, are the contraction of the pupil, generally uncertain in man; the slowing of the pulse, the increased flow of saliva, and the tetanus of the bowels. We must remember, however, that we have scarcely to do with a pure muscarin poisoning which should show all these symptoms, but with an intoxication from a mixture of bases similar to muscarin, yet in many respects differing from this in their action.

It is unfortunate for the comparison of the two, that the clinical picture after burns has been so incompletely studied, and exact observations are wanting as to the condition of the heart, the respiration, the pupil, the accommodation, the peripheral nerves, striped muscle, etc.

The acceptation of an intoxication from putrefactive poisons explains also a paradox, long recognized, but not explained by the other theories. This is the fact that deep burns which cause charring are relatively less dangerous than those which produce only white eschars. After the long-continued action of a high temperature, as for example that of a flame, either complete charring occurs, or a more or less deep browning, which means the impregnation of the tissue with antiseptic tar like products of dry distillation. In every case a tissue so changed is unadapted for undergoing putrefactive decomposition. It shrinks, becomes mummified, and is finally cast off by a demarcating inflammation. We see the same in cauterizations by concentrated sulphuric and hydrochloric acids, the eschars so formed being aseptic, and the importance of the case depending entirely upon the surgical injury; while in cauterizations with calx viva or caustic alkalies, the same points hold as in the case of white eschars.

In developing these views I undertook in one case (in Professor E. Ludwig's laboratory, in Vienna) the chemical examination of an eschar, with slight, although not negative, results. About one-third of the skin of the thigh, so burned as to form a white eschar, was subjected to Brieger's procedure ("Ptomaïnes," Part III.). The peptone-free aqueous extract, obtained by the alcoholic sublimate precipitation, showed the general ptomaïne reactions, but gave no marked poisonous reaction when applied to the heart of a frog, or injected into a rabbit. In explanation of the negative results, two points must be considered: First, the insufficient amount of the material obtained; second, the fact that the methods used are not adapted for small quantities, and this is especially true of the repeated employment of high temperatures for concentrating the extracts. Brieger's method is less well adapted for quantitative results than for isolating particular ptomaïnes, and for this, as a rule, larger quantities of the material are required. It seems to me that further examination of eschars would be followed by better results if experiments were made with alcoholic extracts, or a shaking process, which a greater amount of material would render easier, or with acid aqueous solutions at a low temperature. The latter procedure was used by Brieger and Fraenkel in getting the toxalbumine of the diphtheria and tetanus bacillus. (I was unable to complete a second examination because of my departure.)

As is known, there exists between atropine and muscarin a classic antagonism, in that atropine, when given in proper doses prophylactically, or after the muscarin intoxication, neutralizes the toxic symptoms by paralyzing the nervous apparatus which the muscarin has irritated. It seemed proper to make use of this physiological fact for a therapeutic experiment. At the Vienna Dermatological clinic a young girl was received with extensive burns of the second degree, and superficial burns of the third, caused by her clothing having taken fire. On the second day, the patient being in Hebra's water-bed, ominous symptoms came on, vomiting being the first. I began the subcutaneous injection of sulphate of atropine, and gave within two days five milligrammes. The vomiting ceased after the first injection, the threatening symptoms subsided, and the patient recovered. When it is remembered that Hebra, Sr., and Kaposi, with their extraordinary experience in this field, saw no case of burn recover when vomiting had once occurred, this single positive observation deserves particular attention, and appears adapted to support a theory *e juvantibus*.

In two other very severe cases atropine undoubtedly kept the vomiting in check for hours, and influenced the

[1] Welti, Silbermann.

[2] Ptomaines, iii., p. 26.

other symptoms favorably, without preventing, however, the lethal ending.

This therapeutic employment of atropine is to be considered a first experiment in combating, by means of physiological counter-poisons, the action of the toxic substances formed by decomposition processes and infectious diseases, by delaying the deleterious action of toxines, especially on the nervous system, until the organism shall have had time to overpower the injurious substances. The further development of such a rational therapy depends on the extension of our knowledge of the ptomaines in general, and this applies also to Brieger's theory, "that after learning the constitution of the ptomaines, we can introduce into the system atom groups which will combine with the injurious substances to form non-poisonous compounds."

From the great progress which our knowledge of the decomposition products of the micro-organisms has made in the last few years, we may conclude that the systematic realization of both these will soon come within the range of probability.

In conclusion I would offer some general reflections on the local therapy of burns, which are in part the results of my own experience, in part deductions from the views advanced above.

For the hopeless cases, Hebra's continuous bath best fulfils the sole indication, euthanasia; in cases in which the prognosis is doubtful, I do not consider its employment advisable, since warmth and moisture favor the development of putrefactive processes.[1]

The therapeutic efforts should be directed to the prevention in every possible way of putrefaction in the eschar. Whether this may be accomplished by antiseptics in a narrow sense, especially in the case of thick eschars, is questionable, apart from the danger of intoxication in the employment of antiseptics on a large extent of surface. Even iodoform, for which von Mosetig pleads so warmly, is not able to prevent, in most cases, the putrefactive fluidification of the necrotic skin. Notwithstanding this, experience speaks in favor of external disinfection with iodoform powder, and a gauze bandage without oiled silk. This treatment finds support again in the observation of Brieger, that iodoform prevents the formation of cadaverin in putrefaction; which observation demonstrates a marked influence of iodoform on the chemistry of putrefaction.

Another point worthy of consideration is the local abstraction of water in order to render the eschar dry. Dressings of hygroscopic powders, analogous to the mixture of plaster of Paris and tar, would commend themselves for trial, and especially combinations of magnesia perhaps with the addition of iodoform, or other antiseptics.

A mixture of one part magnes. carb. and two parts oleum rusci, which I have seen used by Dr. A. Hock in Vienna, for certain cases, seemed to me well adapted for this purpose.

Finally, a radical procedure, which as far as I know has not been undertaken, seems to be justifiable, that is, the surgical removal of the necrotic portion of the skin. The cases in which this would be done are especially injuries of small extent which show a tendency to follow a dangerous course. The surgical interference might be delayed until, in spite of local and internal therapy, singultus and vomiting come on, the ominous significance of which justifies any therapeutic expedient.

15 East Sixty-second Street.

The Population of France, according to the offical census, is 38,095,150, an increase of only 208,584 since the previous census.

[1] I would remark incidentally that "Hebra's water-bed" does not seem to have come into so general use as it should. Besides the generally known indications, such as burns, carious processes, decubitus, etc., too little attention is given it (even in Vienna) in other directions, as, for example, in inflammatory and traumatic processes of the spinal cord and column, in which it secures the removal of the weight of the body, which is the chief desideratum.

Progress of Medical Science

The Relation of the Weight of the Placenta to the Weight of the Child.—J. H. Smith, Assistant in the Frauen-klinic, Munich, took the opportunity of searching the records of five hundred births to obtain statistics regarding the relative weight of the child and the placenta; the results have been incorporated in a series of elaborate tables, from which he draws the following conclusions: The placenta being completed at the sixteenth week, a study of its relative size may begin approximately at the seventeenth week. In the cases observed, the average weight of the placenta to that of the child was one-third from the seventeenth to the thirty-second week. Between the thirty-second and thirty-third week the placenta attained its acme of weight, and remained stationary at this point unless influenced by derangements of the fœtal circulation, until birth at the fortieth week. Thus, during the thirty-third and thirty-fourth week the ratio remains one-third; during the thirty-fifth, thirty-sixth, and thirty-seventh weeks, it is one-fourth; in the thirty-eighth and thirty-ninth, one-fifth; and at the end of the thirty-ninth, two-ninths. From the end of the thirty-ninth week until birth, whether labor occurs at the fortieth week or is delayed until the forty-fourth, the ratio remains one-fifth. After the fortieth week the placenta seems to grow rapidly in multiparæ, or with women having large children, thereby raising the average from one fifth to one-fourth.—*The American Journal of the Medical Sciences*, July, 1891.

Incompatibles of Antipyrine.—According to Millard and Campbell, the following substances produce precipitates when added to aqueous solutions of antipyrine: Carbolic acid in saturated solution, tannin (a white insoluble precipitate), mercuric chloride (a white precipitate, soluble in an excess of water), infusion catechu, infusion cinchona-bark, infusion rose-leaves, infusion uva ursi, solution of extract cinchona-bark, tincture catechu, tincture cinchona, tincture hamamelis, tincture iodine (a precipitate soluble in water), tincture kino, tincture rhubarb. The following substances produce coloration when added to aqueous solutions of antipyrine: Hydrocyanic acid, dilute solution, yellow; nitric acid, dilute solution, weak yellow; ammonia-alum, dilute solution, dark yellow; amyl nitrite, acid solution, green; nitrous ether, alcoholic solution, green; copper sulphate, green; ferrous sulphate, yellow-brown; ferric sulphate, blood-red; ferric chloride, blood-red; syrup iodide iron, red-brown.

The Quinine Treatment of Pertussis.—Dr. Ungar advocates anew the employment of quinine in the treatment of whooping-cough. The author thinks that not enough attention has been given to the value of this alkaloid in the affection named, considering that it can considerably ameliorate the violence of the attacks, shorten the course of the disease, and prevent complications. The reason why some authors have not obtained satisfactory results with the remedy the author traces to the use of too large doses. As a rule he gave daily twice as many centigrammes as the child was years old, and as a rule did not exceed eighteen grains daily. Of course, an important factor in determining the dosage is the general physique and health of the patient. Dr. Ungar specially warns against a too rapid diminution or suspension of the use of quinine when the desired effect is produced, as in that case the patient may have a serious relapse. He regards it as a particular advantage of the quinine treatment that pulmonary complications were much less frequent. He never observed any unpleasant effects upon the digestive apparatus, or on the organs of hearing. Though in some cases a very rapid cure was produced, in others it required three or four days of the treatment before the attacks were found to diminish in intensity, and in about a fortnight the disease was practically cured.—*Deutsche Medicinische Wochenschrift.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

MODIFICATION C B.

THOUGH tuberculin has proved so complete a failure therapeutically, it still excites legitimate scientific interest, and a paper by Dr. William Hunter (*The British Medical Journal*, July 25th), giving the result of a chemical as well as clinical study of this substance, deserves serious attention.

Dr. Hunter, as the result of chemical analyses, concludes that the chief substances in tuberculin are:

1. Albumoses; chiefly protoalbumose and deuteroalbumose, along with heteroalbumose, and occasionally a trace of dysalbumose.
2. Alkaloidal substances; two of which can be obtained in the form of the platinum compounds of their hydrochlorate salts.
3. Extractives; small in quantity, and of unrecognized nature.
4. Mucin.
5. Inorganic salts.
6. Glycerine and coloring matter.

So far as Dr. Hunter's observations go, the following substances are absent from tuberculin, namely, serum albumin, globulin, peptones.

The conclusions regarding these substances are summarized as follows:

1. Tuberculin owes its activity not to one principle, but to at least three, and probably more, different substances.
2. Its action in producing local inflammation, fever, and general constitutional disturbance is not a simple, but an extremely complex one.
3. Its active ingredients are of the nature of albumoses, alkaloidal substances, and extractives. The action of these is in certain instances antagonistic.
4. Its remedial and inflammatory actions are connected with the presence of certain of its albumoses, while its fever-producing properties are chiefly associated with substances of non-albuminous nature.
5. The albumoses are not lost by dialysis, the latter are. By the adoption of suitable methods it is thus possible to remove the substances which cause the fever, while retaining those which are beneficial in their action.
6. The fever produced by tuberculin is thus absolutely unessential to its remedial action.
7. The same holds true, I would fain believe, with regard to the inflammation produced by it. Inflammation is certainly not absolutely necessary for the manifestation of its remedial action. It is in some cases, however, beneficial, and helps, under certain circumstances, the action of the remedial substance.
8. The difference between the substance which causes the inflammation and the one which possesses the remedial properties, as regards their action, is not merely one of degree. The local reaction which occurs with small doses of the former is much greater than that producible by large doses of the latter.
9. Nevertheless, the remedial substance has as truly a local action as the one which tends to produce inflammation. This is evidenced in two ways—first, by distinct and obvious shrinking of the tuberculous tissues; and secondly, increased scaling, pointing to the existence of a certain amount of deep local congestion. In some cases this congestion becomes obvious by slight superficial reddening.
10. The power of favoring recurrence, which tuberculin possesses, is connected partly with the non-albuminous substances removable by dialysis, possibly also with a portion of the albumoses present.
11. The remedial substance resists the action of high temperatures. Its action is, however, lessened if exposed to a temperature above 70° C. in a dry condition. Its properties, moreover, can be altered in other ways, sometimes, for example, materially by dialysis. This change is not due to the passage of the substance through the membrane, but to changes occurring in it within the dialysator. Its sensitiveness in this respect I regard as one of its chief features, and causes its preparation to be attended with special difficulties.
12. Both it and the albumoses present probably belong to the class of proteins—albuminous substances derived from the plasma of the bacilli themselves, and not merely formed by the action of the bacilli on the surrounding tissues.

Dr. Hunter, in connection with Dr. Watson Cheyne, used for therapeutic experiment four modifications of tuberculin, called respectively modification A, C, C B, and B; or, tuberculinose A, C, C B, and B.

Modification A acts much like the original-package tuberculin.

Modification C contains the remedial agent, but also a fever-producing substance.

A and C are not recommended for use therefore.

Modification C B contains the remedial substance present in C, freed from the fever-producing and other bad properties of the latter. It fulfils the first condition in having a remedial action, the second in its action being, so far as yet observed, free from any ill effects, and its power of favoring recurrence of the disease is materially lessened, if not abolished.

Its remedial action is unattended with any local reaction other than a slight degree of reddening, and that not always. It is slower probably for this reason than that of B. This absence of inflammation gives it, however, great advantages if it be employed for internal tuberculosis.

Modification B contains the remedial properties of C B with the additional property of inducing local inflammation. Its action is free, so far as has yet been seen, from any ill effects.

Dr. Hunter's hopes seem mostly centred on "Modifi-

cation C B," and a further report of his studies upon its effects was to have been given at the meeting of the British Medical Association.

THE AMBULANCE SYSTEM OF NEW YORK.

The Grand Jury has been investigating our city's ambulance system, and has produced a report upon this subject which is most creditable to the Jury, and one that should interest the medical profession. The facts regarding the work of the ambulances are carefully collected and presented in detail. The following table gives at a glance an idea of the enormous importance and activity of this form of medical service. It represents the work done in the year 1890.

Hospitals.	Total No. Calls.	Highest 1 day.	Lowest 1 day.
St. Vincent	1,930	23	2
Manhattan	567	6	0
Chambers Street	2,678	21	0
Presbyterian	1,202	12	1
New York	1,321	12	1
Roosevelt	1,513	11	0
Total	9,211		
Bellevue	4,246	26	3
Gouverneur	2,374	21	0
Harlem	1,225	10	0
Total	7,845		

The average daily number of ambulance calls is forty-six, and the total number for the year is about seventeen thousand.

The Grand Jury has very little but praise for the system as a whole, and its recommendations bear on minor points. It advises that the ambulances carry red and blue lights instead of white. It also urges the adoption of a comprehensive system of signal boxes or stations scattered through the streets in large numbers, from any of which an ambulance could be summoned to the prompt relief of an emergent case.

The present methods, however, work fairly well in the vast majority of cases. It rarely requires more than eight or ten minutes, at the utmost, to send the ambulance call, and it is unreasonable to expect that a city should provide a signal on almost every block so as entirely to prevent delay.

The best line in which to work for improvement would undoubtedly be that by which the police could be put in quicker communication with the precinct station.

BRIGHT'S DISEASE AND THE PRESS.

Perhaps nothing more extraordinary and painful, in connection with modern journalism, has happened than the recent attempt to fasten Bright's disease upon the eminent hypochondriacal invalid, Mr. Blaine.

An alleged urinary analysis was shown to a number of physicians in this city. We are informed that in most, if not all, cases it was not stated to what case the analysis referred. Various answers were reported to have been given: "If the analysis you show me is a true and reliable statement, the condition of this man must be very bad indeed," said Dr. McCracken, of Eighteenth Street. "The test that you have shown me," remarked Dr. Cumings, of Nineteenth Street, "suggests that Mr. Blaine is a very sick man." Dr. Hanlon, of Twentieth Street, shook his head and said "it was a bad case." "It indicates a very serious condition of things," said Dr. Asche, of Thirtieth Street. Dr. Rounds, of Thirty-sixth Street, said: "An advanced and serious stage of Bright's disease. It is a shame the analysis should have been published." "Chronic Bright's disease in an advanced stage," said Dr. Biggs, of Twenty-fifth Street. "There is no question of what the fate of the patient will be." "It seems like an impossibility that a man could be in the state indicated and live," remarked Dr. Valentine Mott, of Madison Avenue. "If the analysis be true, and why doubt it?" remarked Dr. Emerson, of Thirtieth Street, "Mr. Blaine naturally cannot be long for this earth." And so on.

As a matter of fact, we are informed on good authority that Mr. Blaine has not got albuminuria or Bright's disease.

WIRING OF THE VERTEBRÆ AS A MEANS OF IMMOBILIZATION IN POTT'S DISEASE.

Dr. B. E. Hadra, of Galveston, Tex., has reported in the *Times and Register* for May 23, 1891, a case of fracture of the vertebra, treated by wiring the spinous processes together, and he suggests this procedure as a means of immobilization for the treatment of tubercular spondylitis. The procedure is as follows: A long skin incision, the centre of which should be over the seat of fracture, is made; next the muscles on either side of the spinous processes are lifted up and drawn aside with blunt instruments, but not more than to allow one to feel the contours of the bones. Then a stout curved needle, armed with wire, is carried through the interspace between the spinous process of a vertebra, and that of the next upper one, as deep as possible; brought out, entered again into the next inferior interspace; brought out on the other side; entered there again into the next lower interspace; carried around the spinous process of the vertebra, and again carried through the middle interspace, meeting the wire where it entered, and well twisted together to a knot. In short, a figure-of-eight loop is carried around the spinous processes which may be repeated as often as seems advisable. In the lumbar portion of the spine simple loops will suffice, as the processes are almost horizontal. Then the wound is closed, with or without drainage. All this can be done in a few minutes. The operation is nearly bloodless, involves no great laceration of tissues, and can be made thoroughly aseptic. The wires are well secured in their position by the ligaments, which remain undisturbed.

The reasoning which would lead to the employment of this procedure in spondylitis is perfectly logical. The disease is almost invariably located in the vertebral bodies, and usually on or near their anterior surfaces, the processes, laminæ, arches, and articular facets are invariably healthy; nearly all mechanical means employed to immobilize the spine aim, by indirect leverage, to transfer the superimposed weight from the vertebral bodies to the articular facets, where experience has shown that it is well borne. In Dr. Hadra's procedure the weight is transferred to the same articular facets, but the leverage

is direct, and the immobilization ought, therefore, to be the more perfect.

Immobilization is the aim and end of all mechanical treatment of Pott's disease, yet all corsets and jackets seek to immobilize by grasping the whole trunk, containing vital organs which cannot for a moment be put at rest, and all skeleton braces act by grasping the pelvis below and the arms above, exerting leverage over the kyphos, with nothing to prevent forward bending and consequent motion above and below this fulcrum. When these mechanical difficulties are borne in mind, it will readily be seen how seductive, on theoretical grounds, is the proposition for directly fastening together the spinous processes. Practically, however, it is doubtful if one would submit himself or his child to the small risks of this operation, when a reasonably good result can be anticipated from treatment by non-operative, mechanical means.

THE CAUSE AND CURE OF BALDNESS.

Baldness, like obesity, is one of those minor evils which could probably be much more thoroughly kept under control, if people would take more pains and begin earlier with their treatment.

Dr. M. Joseph Tyson, who writes upon idiopathic and premature baldness in *The Lancet*, makes some observations which quite corroborate this view. Thus he sums up the causes of baldness as insufficient exposure of the hair to the sun and air, close, ill-ventilated hats, excessive mental work and worry, the influence of heredity, venereal and alcoholic excesses, constant washing, and the neglect of using some oil or pomade. These causes vary in importance in different cases.

It can be seen that his remedy is not a single or simple one.

Children, he says, should as much as possible do without caps, and hats when worn should be of the lightest description. During the hot season, a stouter hat is necessary for the prevention of sunstroke. A head covering should never be worn indoors, in trains, or in closed carriages. The kind of material employed is of importance. In summer and still weather straw appears to be the best, on account of its lightness and permeability. In winter, hats made of light felt, well ventilated and unlined, are to be recommended. The ordinary tall hat, and the thick, heavy, unventilated top hat, cannot be too strongly condemned. Of course, nothing special can be said regarding hereditary or nervous influences. In concluding, however, he mentions a few minor points of treatment which should not be forgotten. Too constant washing of the hair is unnecessary, as well as harmful. Once a week is quite often enough for cleanliness, as well as for maintaining the strength of the hair. The same remark applies to constant brushing, for continual brushing, especially with hard brushes, should be avoided. There is a common notion that greasing the hair is vulgar; so many persons fall into the other extreme, and never apply any pomade at all. After the hair has been washed it is certainly beneficial to apply some form of simple grease or oil. When the head-hair is becoming rapidly thinned, some stimulating material, such as ammonia and cantharides, added to the oil, will increase its good effects.

Dr. Tyson does not take into account one possibly important factor in causing baldness, viz., that of contagion. It has been held on good authority that many cases of baldness are parasitic, and due to micro organisms gathered from unclean brushes and combs.

News of the Week.

The Lannelongue Treatment for Tuberculosis. — In a recent issue we gave a general account of Lannelongue chloride of zinc method of treating tuberculosis. A correspondent of *The Lancet* gives the details of the technique. The strength of the solution is generally, he says, about 1 to 10, of which two or three drops may be injected into each determined point. This operation may be repeated several times, either through the same puncture, or through several different punctures, until from eight to twenty drops are deposited, according to the case. In the cases of articular tuberculosis it is expressly advised that the injections be kept completely clear of the cavity of the joint; but they may be practised in the regions from which the synovial membranes draw their blood-supply—that is to say, over the bone at the level of the cul-de-sac. Any fungosities found among the large ligaments of the joint may be included in the injections, but care must be taken that these latter be not made beneath the skin only. Solutions of 1 in 10 will be found the best for articular fungosities, but the author has used a solution of 1 in 40 only for his pulmonary cases, and 1 in 20 for testicular cases. He finds it best to inject but small quantities, such as two drops, at a time, multiplying the points of contact. The injections, it must be allowed, sometimes cause considerable pain, which may even endure for a very appreciable length of time. After the injection has been made, the first change noticeable is swelling of the diseased and neighboring parts. Little or no œdema of the cutaneous tissues follows, unless the injection be made into the subcutaneous cellular structures, an accident which should be avoided. Sometimes an erythematous blush may be observed, which, however, quickly subsides. At the end of a day or two the next apparent change sets in. It consists in the appearance, or rather undue prominence, of the cutaneous venous system, indicating the obstruction to the deeper circulation which follows the destruction of the vessels of the altered tissues. There is rarely or never any effusion into the joints as a result of the injections, provided of course that these cavities be carefully avoided. Palpation will detect a modification in the involved tissues the day following the injections. The irritation thus set up is at first quite localized, but soon propagates to remoter areas, indicating, in the opinion of the author, that there is not merely a diffusion of liquid, but an actual transportation of the irritated or inflammatory process along the vascular channels. The fungous growths become more consistent, and within the lapse of four days nodules quite hard and almost cartilaginous appear over the seat of each injection. The general health of the patients treated is little or not at all affected by the injections, the temperature rarely passing 39° C. (102.1° F.) The weight of the patients is not modified while under treatment, but a distinct gain is noticeable as soon as the treatment is terminated. As to complications attending

the method, they may be said to hardly exist. Sometimes a subcutaneous or intermuscular effusion of blood takes place, owing doubtless to minute vascular ruptures resulting from the intense congestion and friability of the smaller vessels. These vary from the size of a pea to that of a large nut, and may be mistaken for small abscesses. They are, however, of no great moment, and usually disappear under the influence of continued pressure. In over two thousand injections made by the author there was not one case of abscess, antiseptic precautions being, of course, strictly observed in all cases. With a 1 in 10 solution a scar may follow, especially if the injection be made under the skin only; but with weaker solutions, or where the injection is carried sufficiently deep, no such complication results. When they do follow they are rarely larger than a ten-cent piece, and involve the skin only at the seat of injection. In the case of suppurating but unopened joint cases, M. Lannelongue first aspirates the cavity and then washes it well out with sterilized water, after which he injects the solution into the periphery in several points. Sometimes the cavity refills with pus, and the abscess may open; at other times the reproduced effusion may not be purulent. In cases of tubercular bone disease with a sequestrum, a sclerosis is set up in the tissues surrounding the sequestrum, but a complete disintegration of the caseous products follows. An inflammatory action would appear to be excited in the tissue surrounding the sequestrum, which is characterized by a phlegmonous process ending in an abscess. Operative procedures are not, therefore, suppressed or superseded; on the contrary, once the sclerotic change is completed the bony parts are in the best condition for such measures, to which recourse may then be had without fear of lighting up further infection in healthy parts beyond.

A Slight Reaction in Favor of Tuberculin is reported to have set in at Berlin. Professor Ehrlich, who is to read a paper on the subject before the Congress of Hygiene, in London, next week, believes in the efficacy of the lymph. He says that he had tubercle bacilli in his sputum, but that they entirely disappeared after a few very mild inoculations.

An Army Medical Board will be in session in New York City, during October, 1891, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before September 15, 1891, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a Regular Medical College, as evidence of which, his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, Washington, D. C.

American Laryngological Association.—The following papers will be read at the thirteenth annual congress of the American Laryngological Association, to be held in the city of Washington, D. C., September 22, 1891: "A Case of Thyrotomy in a Child Eighteen Months Old," by Dr. Clinton Wagner, of New York; "Some of the Uses of Pyoktanin in Diseases of the Upper Air-passages," by Dr. R. P. Lincoln, of New York; "The Troublesome Symptoms Caused by Enlargement of the Epiglottis, and the Advisability of Reducing the Size of this Cartilage by Operative Measures," by Dr. Clarence C. Rice, of New York; "The Surgical Treatment of Tubercular Laryngitis," by Dr. D. Bryson Delavan, of New York; "Various Forms of Disease of the Ethmoid Cells," by Dr. F. H. Bosworth, of New York; "A Case of Epithelioma of the Larynx," by Dr. Morris J. Asch, of New York; "Useful Deductions Derived from the Study of a Case of Cicatricial Contraction of the Larynx, possessing Unusual Clinical Features, with Exhibition of Specimen," by Dr. W. C. Jarvis, of New York; "Three Obscure Cases of Syphilis of the Nose," by Dr. Charles H. Knight, of New York; "Nasal Papillomata," by Dr. Jonathan Wright, of Brooklyn; "A Case of Foreign Body in the Trachea," by Dr. W. C. Glasgow, of St. Louis, Mo.; "The Tonsil in Health and Disease," by Dr. Harrison Allen, of Philadelphia, Pa.; "Observations on Paralysis of the External Tensors of the Vocal Cords," by Dr. George W. Major, of Montreal; "The Laryngo-Tracheal Neoplasms of Tuberculosis," by Dr. John N. Mackenzie, of Baltimore. Charles H. Knight, *Secretary*.

Professor Rubner, from Marburg, has been appointed Koch's successor as director of the Hygienic Institute in Berlin, and will enter upon his new duties on October 1st.

Association of American Physicians.—The following papers will be read before this Association at its meeting in Washington in September: "President's Address," by Dr. William Pepper, of Philadelphia; "Discussion on the Treatment of Visceral Tuberculosis by Koch's Method,' Reports by Drs. F. P. Kinnicutt, of New York; Harold C. Ernst, of Boston; William Osler, of Baltimore; Musser and Griffith, of Philadelphia; "The Climate of Southern California for Respiratory Diseases," by Dr. Norman Bridge, of Los Angeles; "Experimental Studies on the Causes of the Localization of Pulmonary Phthisis and certain other Infectious Diseases in the Lungs," by Dr. J. W. Roosevelt, of New York; "Discussion on the Remote Results of the Removal of the Ovaries and Tubes," *Referee*, Dr. William T. Lusk, of New York; *Co-Referee*, Dr. Wharton Sinkler, of Philadelphia; "Nerve Stretching in Inveterate Cases of Trigeminal Neuralgia," by Dr. James Stewart, of Montreal; "On the Diseases of the Kidney, popularly called 'Bright's Disease,'" by Dr. Francis Delafield, of New York; "Note on the Recognition of Certain Cases of Epilepsy, accompanied by Albuminuria, which might be mistaken for Cases of Uræmic Convulsions," by Dr. James Tyson, of Philadelphia; "Bradycardia in Acute Articular Rheumatism," by Dr. I. E. Atkinson, of Baltimore; "Discussion on the Relations Between Arterial Disease and Visceral Changes," *Referee*, Dr. George L. Peabody, of New York; *Co-Referee*, Dr. W. T. Councilman, of Baltimore; "Intes-

tinal Perforation in Typhoid Fever," by Dr. R. H. Fitz, of Boston; "The Relation of Drinking-water to Disease," by Dr. Henry P. Walcott, of Cambridge; "A Contribution to the Pathology of Pernicious Anæmia," by Drs. J. P. Crozer Griffith and Charles W. Burr, of Philadelphia; "On Changes in the Red Blood-corpuscles in the Pernicious Anæmia of Texas Cattle Fever," by Dr. Theobald Smith, of Washington; "The Condition and Prospects of the Library of the Surgeon-General's Office, and its Index Catalogue," by Dr. John S. Billings, of Washington; "Sequel to a Case of Slow Pulse (Purdy)," by Dr. D. W. Prentiss, of Washington; "Report of Autopsy," by Dr. Robert T. Edes, of Washington; "Grave Forms of Purpura Hæmorrhagica," by Dr. J. H. Musser, of Philadelphia; "Pathological Histology of Acute and Chronic Appendicitis," by Dr. William F. Whitney, of Boston; "The Treatment of Typhoid Fever by Systematic Cold Bathing," by Dr. James C. Wilson, of Philadelphia. The Association will hold its meeting in Hall No. 1 of the Grand Army Building, 1412 and 1414, Pennsylvania Avenue; and in the Main Hall of the same building the meetings of the Congress will be held.

Congress of American Physicians and Surgeons.—The following are the subjects announced for discussion at the sessions of the Congress of American Physicians and Surgeons, to be held in Washington on September 22d, 23d, 24th and 25th. The sessions will be held at 3 P.M., each day: "Conditions Underlying the Infection of Wounds, including a Discussion of Disinfection with Reference to the Treatment of Wounds, of the Relation of Bacteria to Suppuration, of the Resistance of Tissues to the Multiplication of Bacteria, and of the Effects of Antiseptic Agents on Wounds," *Referee*, Dr. William H. Welch, of Baltimore; *Co Referee*, Dr. Roswell Park, of Buffalo. 2. "The Late Manifestations of Syphilis," *Referee*, Dr. Phineas S. Conner, of Cincinnati; *Co Referee*, Dr. Abner Post, of Boston. 3. "Fibroid Processes (Chronic Interstitial Inflammation Scleroses): Their Pathology and Etiology, with Special Reference to the Influence of Diathesis and Heredity," *Referee*, Dr. A. L. Loomis, of New York City; *Co-Referee*, Dr. William Osler, of Baltimore.

The "Fatal Patient."—We have received several letters regarding the story of the fatal patient published in the MEDICAL RECORD of July 25th. We have not space to publish all, nor is it necessary. The essential facts communicated are that while Dr. Wendell Phillips is alive, Dr. David Phillips, who treated the patient, was found dead in his bed the next morning. When the patient was turned over to him, Dr. Phillips remarked that he supposed he would be the next victim; and so he was. The coincidence was remarkable. We are indebted to one correspondent for some notes regarding the late Dr. Phillips. He graduated from the College of Physicians and Surgeons of New York in 1873, was Assistant Surgeon to the Manhattan Eye and Ear Hospital, and also Nose and Throat Surgeon to the Yorkville Dispensary, at the time of his death. He served six years on the staff of the Northwestern Dispensary. He was a member of the New York County Medical Association and the Metropolitan Medical Society. About three months ago he wrote an article on "Ichthyol in the Treatment of Atrophic Rhinitis," which he read before the Laryngological Section of the Academy, although not a member. This article was published in the *New York Medical Journal*. He was about thirty-eight years of age.

Honors.—Dr. W. W. Keen, of Jefferson Medical College, has received the honorary degree of LL.D. from Brown University.

Dr. D. G. Brinton, formerly of the *Philadelphia Medical and Surgical Reporter*, has received the degree of LL.D. from the Jefferson Medical College, in recognition of his researches in anthropology and ethnology.

Appointments.—Dr. Victor C. Vaughan is made Dean of the Faculty of Medicine in the University of Michigan, in succession to Dr. Ford, who has resigned.

The Board of Trustees of the Philadelphia Polyclinic and College for Graduates in Medicine have created a third Chair of Diseases of the Eye, and, upon the unanimous nomination of the Faculty, have elected Professor George de Schweinitz, M.D., to fill the position.

Dr. J. P. Crozer Griffith has been elected Clinical Professor of the Diseases of Children in the University of Pennsylvania.

Dr. Condict W. Cutler, of New York, has been appointed Professor of Skin and Venereal Diseases in the University of Vermont, to succeed Dr. R. W. Taylor, who has resigned.

A Cure for Viper Bites.—The Academy of Medicine of Paris has awarded the Orfila prize to Professor Kaufman, of the Veterinary College, at Alfort, for a lotion for the cure of viper bites, consisting of one part of chromic acid dissolved in one hundred parts of water.

The Use of Vaginal Injections.—Dr. Doderlein, of Leipsic, states that he has examined the secretions of a large number of healthy women, and although germs were found, they were never pathogenic. He never found the staphylococcus. From his observations he draws the practical conclusion that disinfection of the healthy vagina is not necessary, whether internal examinations have been made during labor or not. There are, however, persons who syringe as a routine practice, and will probably continue to do so in spite of the plainest proof that it is unsound midwifery. In the pathological secretions of one hundred and fifty six cases he found the streptococcus pyogenes six times. In such cases it is of great importance to bring about an acid reaction in the vagina, and the chief danger to the patient is in making internal examinations.

Bequests to Medical Charities.—By the will of Hector C. Havemeyer, several of our local medical charities will be benefited as follows: Post-Graduate Medical School and Hospital, $5,000; the Manhattan Dispensary and Hospital, $5,000; Presbyterian Hospital, $5,000.

The Medical Society of Virginia meets at Lynchburg in October.

The Mississippi Valley Medical Association will hold its seventeenth annual session at St. Louis, Wednesday, Thursday, and Friday, October 14, 15, and 16, 1891.

Koch's Lymph in Colorado.—Several Koch hospitals have been established in the United States, but with varying success, except that in Denver, which, according to the *Denver News*, seems to have been an unqualified success.

Gout and Fruit-eating.—In the last number of his *Archives of Surgery*, Mr. Jonathan Hutchinson says that he has for many years been in the habit of forbidding fruit to all patients who suffer from tendency to gout. In every instance in which a total abstainer of long standing has come under his observation for any affection related to gout, he has found on inquiry that the sufferer was a liberal fruit eater. Fruits are, of course, by no means all equally deleterious; cooked fruits, especially if eaten hot with added sugar, are the most injurious, the addition of cane- to grape-sugar adds much to the risk of disagreement. Fruit eaten raw and without the addition of sugar would appear to be comparatively safe. Natural instinct and dietetic tastes have already led the way in this direction, few wine-drinkers take fruit or sweets to any extent, and Mr. Hutchinson suggests as a dietetic law that alcohol and fruit-sugar ought never to be taken together; and he believes that the children of those who in former generations have established a gouty constitution may, though themselves water-drinkers, excite gout by the use of fruit and sugar.

Russian Female Physicians have apparently been restored to the good graces of the Czar. A recent ukase permits female physicians to practise everywhere within the Russian empire, provided they wear a badge supplied by the crown, indicative of their calling. Moreover, women are to enjoy special privileges of practising in female hospitals, as well as charitable institutions, gymnasia, and schools for young women. The ukase lays down special regulations for the appearance and testimony in court of female physicians, so that womanly modesty shall not be outraged by impertinent cross-examination.—*Medical Standard.*

Seymour, Ind., has a boy who has just awaked from a continuous sleep of one hundred and nine hours. That youth's talent is wasted in the wild and woolly West. He should come to Philadelphia.—*Times and Register.*

The Fiske Prize.—The Trustees of the Fiske Fund have awarded a prize of $300 to Dr. Robert W. Lovett, of Boston, for an essay on "The Etiology, Pathology, and Treatment of the Diseases of the Hip-joint."

Grafting Cancer—A Medical Scandal.—The *British Medical Journal* says: "When we read in the *Echo de Paris*, of June 26th, a paragraph headed, 'Le Scandale de l'Académie de Médecine,' we hoped that the story which it told was either wholly untrue, or, at the worst, grossly exaggerated. The *Bulletin* of the Académie de Médecine, however, published on June 29th, contains the official report of a paper read by no less a person than M. V. Cornil, at the meeting on June 23d. This paper reports proceedings which we can only characterize as an outrage, not only upon the unhappy persons therein referred to, but also upon the whole medical profession. It is a paper to which, if proper supervision had been exercised by the officials, the fictitious importance conferred on it by being read at the Académie would never have been given. The facts of the case are, briefly, that 'un chirurgien étranger,' who conceals his identity, took advantage of the insensibility of two patients, from each of whom he was removing a tumor of the breast, to graft a portion of each tumor into other, and apparently unaffected, parts of their bodies. He states that each of these grafts took effect; in one case the patient died, but not of the grafting; in the other case the patient was still living, at the time of the report four years ago, but she refused to undergo any further operation. We cannot reprehend too strongly such an abominable action as has been perpetrated in these cases; the immorality is obvious, and the scientific result quite valueless."

The Danger of Being too Clean.—Dr. M. Ricketts has discovered a skin affection almost peculiar to women who wash and powder too frequently (*British Medical Journal*). There is redness, with scaliness and considerable burning. Exposure to draughts increases the symptoms. At times there is pain, causing loss of sleep. The zeal of some American ladies in the practice of the virtue which is next to godliness is marvellous. One is said to have confessed to having applied a well-known cosmetic powder thirteen times in twelve hours, each time after the face had been thoroughly washed with a yet more famous soap. Dr. Ricketts prefers good, pure olive oil from the south of France, applied two or three times a day with some soft silk or linen fabric, to the blandest soap.

Fiat Cauda Galli.—A clever convalescent in the University Hospital borrowed a United States dispensatory, and wrote a regular prescription for a matutinal cocktail, with the appropriate Latin formula for the ingredients. His ingenuity was rewarded, the prescription was put up and delivered, and the order, with its "fiat cauda galli," now hangs on the druggist's hook.—*Times and Register.*

The Regents of the State University and the Board of Medical Examiners.—Says *The Post Graduate*: "The MEDICAL RECORD seems to think that the law [creating a State Board of Medical Examiners] was amended because of the 'stupidity and weakness' of the Board of Regents in not appointing any examiners from New York City. That this was an absurd and unexpected action of the Regents is certainly true. We now know why Governor Hill once wished to abolish them, perhaps; but we fancy that the mine of the Long Island College Hospital was well laid long before the Regents appointed the examiners, although its explosion occurred just afterward. As to who handled the Board of Regents, as the RECORD felicitously puts it, we think that the distinguished homœopath from Utica, who is a member of the Board, can tell as much about it as any one. Next year we hope the Regents will condescend to appoint at least one New Yorker, or the State Society, in strict compliance with law, may conclude to send in only the names of New York practitioners from which the Regents must choose. We can look out for sharp practice, if we must. The members of the profession outside of New York City, with possibly the exception of those in one important town not a thousand miles from the capital, have no desire to see New York City, through whose efforts a State Examining Law was finally passed, humiliated by their contemptuous exclusion from the board which they solidly voted for."

Not so Slow after all.—A remarkable case of early precocity has been made public in Philadelphia, where a girl of sixteen gave birth to a child whose father, at the time of conception, was only thirteen years old.

Society Reports.

INDIANA STATE MEDICAL SOCIETY.

Forty-second Annual Session, held at Indianapolis, June 10 and 11, 1891.

The meeting was largely attended, two hundred and fifty physicians being present. The reports of the Secretary, Dr. E. S. Elder, Treasurer, Dr. Frank C. Ferguson, and the Committee on Necrology, Dr. J. F. Hibberd, of Richmond, occupied a large part of the morning session the first day.

The Alumni of the Medical College of Indiana celebrated the twenty-first year of its existence by a banquet at the Dennison House, Tuesday evening. More than two hundred of the members were present, and the occasion was highly enjoyable, with both the rich viands and the feast of reason and flow of wit which enlivened the wee small hours.

The officers for the coming year are: *President*, Dr. Edwin Walker, of Evansville; *Vice-President*, Dr. Erwin Wright, of Huntington; *Secretary*, Dr. E. S. Elder, of Indianapolis; *Assistant Secretary*, Dr. T. A. Kennedy, of Shelbyville; *Treasurer*, Dr. J. O. Stiltsee, of Indianapolis. Dr. Edwin Walker, the President, is the youngest man elected to that position for many years.

Bacteriological Investigations.—Dr. Theodore Potter made an interesting report on this subject, in the course of which he said that there is a growing belief that the older ideas of heredity are exaggerated; that disease is to be looked upon as an infection rather than an inheritance; that it is comparatively rarely transmitted from parent to child in course of nature. Yet he added the doctrine of heredity is by no means overthrown, and we must still wait for the whole truth.

Antiseptic Methods Applied to Obstetrics.—Dr. J. W. Milligan, of Indianapolis, read a paper with this title. This was thoroughly discussed, and soap and water received most commendations as the most efficient disinfectant. Puerperal fever had existed for two hundred years, and it is time it is disappearing.

The Salicylic Treatment of Typhoid Fever.—Dr. C. C. Morris, of Rockville, read the paper. He said that salicylate of soda is an acknowledged germicide, and there is every reason for its use in typhoid and kindred diseases.

Dr. J. A. Sutcliffe, of Indianapolis, had an interesting paper on "Perineal Section," with a number of descriptive cases. Following this Dr. C. H. Smith, of Lebanon, treated of "Abortion." He spoke of those cases occasioned by accident or disease, and laid great stress on the patient having absolute physical and mental rest, and then relief from pain.

Dr. Owen read a paper entitled "What should be the Relation of Contract Corporation Surgeons to the Medical Profession?" The subject was referred to a committee consisting of Drs. Owen, Hibberd, and Sutcliffe, with instructions to report before the close of the meeting.

Dr. M. F. Porter, of Fort Wayne, read a "Report of a Case of Sarcoma of the Ovary, Operation and Recovery." After this came a paper by Dr. F. C. Ferguson, of Indianapolis, on "Some Fallacies in Gynecology." The topic "Diphtheria" was handled by Dr. W. A. McCoy, of Madison, and the venerable Dr. Lomax said he had come across the term diphtherite in the beginning of his practice, fifty-four years ago, and the disease soon after, hence it was not a product of modern civilization, as is sometimes supposed.

The Influence of Heredity in Producing Disease and Degeneracy and Its Remedies.—The address of the President, Dr. Gonzalva C. Smythe, of Greencastle, was a very able one. He showed what might be determined from the stand-point of the biologist, and spoke of inebriety as a physical disease which may be inherited, the children of inebriates becoming perhaps epileptic, insane, or criminals. In a large proportion of cases the third and fourth generations from drunkards are criminals or paupers. He said the profession was face to face with one of the greatest problems in sociology which confronts the present day. It is its duty to open up the way so the religious and civil authorities can follow. He proposed for the Government to take the matter in hand and only admit those immigrants who can furnish a consular certificate that neither tuberculosis, scrofula, cancer, insanity, inebriety, crime, or pauperism is hereditary in the families from which they sprung. It is a comparatively easy matter for the Government to exclude from admission any more of these people thus diseased, but how to dispose of the stock now on hand will tax the best minds of the country. The State interposes no objection to the marriage and multiplication of these people. She licenses and legalizes a traffic which largely contributes to their propagation and the influence of which will be handed down to posterity. It is the duty of the Government, as a sanitary measure, to assume entire control of the manufacture and sale of alcohol. Every attribute of the human family might be improved and new ones be possibly developed were science brought to the aid of sentiment in mating the sexes.

Hysteria.—This was the first paper of the second day's session, by Dr. A. B. Richardson, of Cincinnati. The manifestations of the disease he called "fugacious," and compared it to the cuckoo building no nest of its own but steals into those prepared by other physiological processes.

Dr. J. R. Weist, of Richmond, reported the lamentable failure of the two bills before the last Congress in which this society had special interest. One of these was to protect physicians, editors, and others against speculative lawsuits, the other for the regulation of expert medical testimony in court.

Dr. A. W. Brayton, of Indianapolis, presented a girl, fourteen years of age, afflicted with the extremely rare disease of the skin known as xeroderma pigmentosum, Kaposi's disease. This is the only case ever known in the Mississippi Valley and the eleventh known in the United States.

One Phase of Puerperal Sepsis.—Dr. Edwin Walker, of Evansville, Ind., read a paper upon a special form of chronic puerperal septic infection. The following is a short abstract: Midwives furnish most of the cases of puerperal fever. The intelligent physician who applies modern principles rarely has one. Puerperal sepsis is the result of the introduction into the genitals of a specific poison. This may enter the circulation by lacerations or extend to uterus, tubes, or peritoneum. The first thing is to determine the location of the poison and to remove when possible. The special class of cases referred to in this paper is that in which the morbid material forms a focus of inflammation involving the tubes and peritoneum.

In patients suffering from this condition the tumor felt in the pelvic region has been shown to be formed of an enlarged and inflamed tube (or sometimes both tubes are found to be in the same condition), and of adherent coils of intestine whose peritoneal investment is in an inflammatory state. It not infrequently happens that the process has gone on to suppuration, in which case pus is present and contributes to the formation of the tumor.

The speaker reported three cases of this nature in which resort was had to abdominal section. The adherent intestines were carefully separated from the diseased tubes and the later were then removed. All of the patients recovered.

Cases of this nature were formerly erroneously regarded as instances of cellulitis and although they usually recovered it was only after a long and tedious illness lasting many months, with intervals of improvement followed by discouraging periods of recrudescence of the inflammatory symptoms. Sometimes, however, and this not infrequently, such patients never wholly recovered, but went to increase the number of chronic invalids.

A case was cited which lay for twelve weeks with fever; a tumor was present. This was five years ago and an operation was not done. Recovery was tedious. An early operation would have saved much suffering and the patient would be in better health now. The rule in all cases of puerperal sepsis where fever continues and tumor is found, is to remove it by laparotomy. With proper precautions the mortality would be less than by the expectant plan and the recovery more rapid and complete.

Some Fallacies in Gynecology was the subject of an able paper read by Dr. Frank C. Ferguson. He said that twenty-five years ago gynecology was in a crude and chaotic state; there were a hundred fallacies to one well-authenticated fact. Sims, in our country; Baker Brown, in England, and Simon, of Germany, laid the foundation upon which has been built the rational and scientific treatment of diseases peculiar to women, but the fallacies which were once taught as facts have taken such deep root in both the professional and non-professional mind that many physicians have failed to appreciate or adopt the modern advances in gynecology which have exploded much of the pathology of the writers of former years. The pessary fallacy is a more pernicious one. An era of pessary invention was ushered in by Professor Hodge, who adopted the theory that displacements of the uterus were the cause of almost all uterine ailments and who introduced the treatment by mechanical appliances. The pessary craze still has a firm hold, not only upon women, but clings tenaciously to the majority of the profession. There are some cases where a well adjusted pessary serves a good purpose as an adjunct to the cure or promoter of the comfort of the patient, but the indiscriminate, unscientific, and perhaps criminal use of pessaries by amateur gynecologists, and physicians experienced in general practice but unskilled in gynecology, is only mentioned to be condemned in the strongest terms.

Another fallacy is, "the ulceration of the os" fallacy. However much our predecessors may have been justified in calling "ulceration" that characteristic affection of the uterus now known as "laceration," there can be no excuse to-day for the perpetuation of this erroneous idea.

Another fallacy is, that laceration of the cervix neces sarily requires an operation for its cure. While I believe that Lawson Tait has gone too far in denouncing Em met's operation as one of the most useless ever invented, my own experience has taught me that the great majority of cases of laceration of the cervix can be cured without subjecting the victims to a dangerous operation and inconvenience of enforced confinement in bed for weeks. What is there in the anatomical structure of the cervix that can prevent nature from promptly healing it, provided there be not an acrid discharge pouring over the torn surface. During the past year I have operated upon but one case of laceration of the cervix and have cured a dozen cases without operation.

A wide-spread fallacy among physicians, and entertained almost universally among women, is that the "change of life" is necessarily a period of peculiar peril and intense suffering. Nothing could be farther from the truth and more harmful in its results. If a woman have good health and no organic disease of the reproductive organs, she will suffer nothing more at this period than slight nervous symptoms, such as flushes, slight headaches, etc., the result of vaso-motor disturbances. If she have pain or hemorrhage, or profuse leucorrhœa, singly or combined, it is almost certain she is afflicted with organic disease, as cancer, fibroid tumor, endometritis, salpingitis, or ovaritis. During the past year four women who had been under the care of excellent general practitioners for "change of life" have consulted me, and each one was found to have cancer of the cervix uteri in an advanced stage. Three of these are now in their graves. It is a fearful thing for a physician to assume to know what he does not, and through the egotism of ignorance become responsible for the death of a confiding and trusting woman.

A fallacy of firm hold in the minds of many is, that pruritis vulvæ is frequently a neurosis, that is to say, that it is of centric origin without any lesions of structure or accompanying affections to account for it. Where uncleanly habits of the patient are not the cause the trouble can be traced to some disease existing in the vagina, the uterus, or the bladder. There are many other fallacies which time forbids to mention.

Dr. G. W. McCaskey read a paper on "Some Needed Medical Legislation." Following this came a paper by Dr. S. M. Voris, of Columbus, on "Lacerations of the Perineum," and one by Dr. G. W. Vernon, of Indianapolis, on "Vulvo-vaginitis in Children."

At the afternoon session papers were read by Dr. F. C. Woodburn, of Indianapolis, on "Valvular Heart Diseases;" S. C. Evans, of Union City, "Nasal and Naso-Pharyngeal Reflexes;" H. McCullough, of Fort Wayne, "Functional Aphonia;" C. L. Thomas, of Logansport, "Cataract, with or without Iridectomy;" Norman Teal, of Kendallville, "Health and Vital Statistics;" S. W. Gould, of Argos, "Opium and its Preparations;" M. F. Johnston, of Richmond, "Angina Pectoris."

When the last paper was read, President Smythe came forward and presented the newly elected president, Dr. Edwin Walker, to the Convention. When the applause which greeted the presentation had subsided Dr. Walker made a short address and the Society adjourned to meet on the second Thursday in May, 1892.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Called Meeting, April 27, 1891.

William T. Bull, M.D., Chairman.

Exostosis of Frontal and Parietal Bones.—Dr. W. R. Townsend presented a man, then fifty-two years of age, who, about seventeen years ago, had fallen downstairs a distance of ten or twelve feet, striking his head on a wooden floor. From that time he had noticed a slow but steady increase of bone growth over the parietal and frontal bones on the left side, the tumor having now attained the size of half an orange or more. It had caused no symptoms. The interest in the case was the slow but steady growth of the bone for so long a time after the injury.

Sarcoma of the Metacarpus with Rapid Generalization.—Dr. W. B. Coley read the history of the case, presented the amputated hand, and gave statistics, with remarks. The patient, a lady, had sustained a blow on the back of the hand, the swelling did not subside, pain became more severe, and she sought the advice of a physician, who treated it as a simple bruise. In the fall of the same year she came to New York, where Dr. Coley saw her, found a fusiform swelling the size of half a dollar over the metacarpal bone of the ring finger, the swelling gradually shading off. Further examination in October led him to think there was subacute periostitis, and an incision was made, but only little, if any, pus escaped, with some blood. The wound was dressed aseptically, but the swelling increased, and Dr. Bull was called in, who thought there was periostitis, probably of tubercular origin. An operation was postponed, but the swelling increased, sensation and motion were lost or impaired, and there being absence of inflammatory swelling, he concluded the case was one of sarcoma. Before microscopic examination of tissue had been completed, the character of the tumor changed, showing that it was undoubtedly sarcoma. The microscopic examination, when completed, revealed round-celled sarcoma. November 8th amputation was performed at the middle of the forearm. While the wound healed readily, yet the general health remained poor, the pulse continued high, 100 to 120. Three weeks after the amputation the patient complained much of epigastric pain, there was a small area of resistance, which became more marked later, pointing to recur-

rence. Four weeks and a half after the operation a small nodule appeared in the right breast. Before death, which took place about six weeks after the amputation, there had been jaundice, vomiting of blood, involvement of the axillary glands, the tumor of the mamma had attained the size of a goose's egg, etc. The rapid dissemination of the disease showed its intensely malignant nature, and its occurrence after an insignificant injury, and the difficulty of making an early diagnosis, impressed the necessity for further study of these cases.

The paper contained a reference to 84 cases of sarcoma, treated the past eighteen years in the New York Hospital, and in the private practice of Dr. Weir and Dr. Bull. The subsequent history of 39 of the cases was given, 26 having a fatal recurrence. Gross had collected a large number (nearly two hundred) cases of sarcoma of the long bones, but of this number none involved a metacarpal bone. Thirteen were periosteal, the malignancy in these cases being greater than where the disease started in the centre of the bone. The chief characteristics of superiosteal sarcomata might be summarized as follows: History of traumatism (present in 7 of the 13 cases collected by Gross and in 3 of the author's) early pain; both pain and traumatism were much more frequent in round-celled than in spindle-celled sarcomata; usually fusiform, seldom encapsulated; tendency to early infiltration; soft, elastic, non-pulsating; in thirty-eight per cent. the lymphatics were enlarged; rapid increase in size; discoloration of the skin in about half the cases; pulse relatively too high for the temperature. Of Gross's 13 only 1 was known to have been cured.

In the author's collection there were 8 cases of undoubted sarcoma of the muscles—4 in the triceps, 1 in the gastrocnemius, the others in the adductors of the thigh. Nearly all recurred within twelve months. It was probable one of Dr. Bull's would remain cured. The tables gave little information regarding heredity. His own patient had an ancestor die of a tumor of the lip, probably an epithelioma.

The author here dwelt somewhat upon the influence of erysipelas on sarcoma. A number of cases had contracted erysipelas accidentally, and had been improved for a time, and many had had no recurrence of the sarcoma. Others had been cured by intentional inoculations with the erysipelas virus. This treatment had been practised to some extent in Germany, very little in other countries, not at all here, although he thought that of the large number of hopeless cases in the several hospitals throughout the land it certainly deserved a trial. Dr. Bull had operated on one case of sarcoma five times in about three years. The last time the tumor recurred quickly, was large, and probably would have proven fatal, but erysipelas developed accidentally, the malignant growth disappeared, and the man had remained permanently cured. Inoculations of the erysipelas virus had also proven of some success in keloid and carcinoma.

The CHAIRMAN made some remarks on the great difficulty of making an early diagnosis of sarcoma, except possibly in sarcoma of the skin. Three or four physicians were likely to treat the case before its true nature would be recognized. In doubtful cases he would recommend early microscopical examination of a section. He thought inoculations with the germ or virus of erysipelas ought to be tried in the treatment of sarcoma in this country, especially in the hopeless cases.

Reproduction of Bone from Blood-clot After Excision of the Knee.—DR. JEWETT presented for Dr. A. M. Phelps, who had a call out of town, two patients, the first one of whom, a girl aged nineteen, gave a family history of phthisis in both parents. At the age of twelve she had an abscess two inches below the knee, which broke and remained open a year. Since then the knee had been tender. When admitted to the Charity Hospital in September last there was pain and swelling over the knee, which increased, and she was unable to stand on the leg. January 3, 1891, Dr. Phelps excised the knee, removing about two inches from the lower end of the femur and two inches of the upper end of the tibia and fibula, saving the periosteum as far as possible. Put the limb up in plaster-of-Paris, dressed to favor bone formation from the blood-clot. The leg was retained in the splint until April. There was an inch shortening. The patient could now support herself on the limb, but used crutches, owing to some soreness at the line of incision through the skin. There was apparently bony union.

Suture of the Wrist-Tendons.—The second patient presented by Dr. Jewett for Dr. Phelps was a young man who had been admitted to the hospital January 29th last, having received a transverse cut across the wrist December 21st. He was treated outside for five weeks, and came to the hospital for correction of deformity resulting from retraction of the tendons. The median nerve had also to be sutured. The tendons had markedly retracted, and become individually indistinguishable. These were united *en masse*. The wrist could now be straightened to nearly a direct line, sensation had been in some degree restored, the motion was somewhat restricted because of restraint until recently by the dressings.

A Vegetable Plate; a New Technique in Lateral Anastomosis.—DR. R. H. M. DAWBARN read a paper, describing experiments which he had made with vegetable plates which should take the place of Senn's bone plates, Abbe's catgut rings, etc., in making lateral anastomosis, especially in emergency cases (see vol. xxxix., p. 725).

The paper was discussed by Drs. Abbe, B. F. Curtis, Samuel Lloyd, and the Chairman. They all thought the potato plate might prove useful, but did not think intestinal anastomosis should be an emergency operation. Better if necessary form a fistula, and leave the more formidable operation until the patient had recovered from shock and its performance seemed necessary. They offered some criticisms upon the new technique which the author said, in closing the discussion, were without practical basis.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 25, 1891.

H. M. BIGGS, M.D., PRESIDENT, IN THE CHAIR.

An Abdominal Tumor.—DR. H. P. LOOMIS presented some tumors which had been removed by operation from a woman, forty-six years of age, who had been in excellent health up to about two years before, when she began to suffer pain in the left side of the abdomen, and this was accompanied by a rapid development of ascites. Up to three months ago she had been tapped four times. At the time of her admission to the hospital the abdomen was greatly distended, and she suffered considerably from dyspnœa. A microscopical examination of the fluid showed nothing characteristic. Various diagnoses had been made—simple ascites, cancer, ovarian tumor, and cirrhosis. On making an exploratory incision, about four gallons of serous fluid gushed out of the abdomen, and in the lower portion of the cavity, these tumors were found floating in the fluid.

The growths were situated upon both sides, being somewhat adherent on the left, and they presented a cauliflower appearance. The Fallopian tube on the left side was filled with blood-stained fluid and it was ligated near to the uterus and removed. The patient recovered promptly from the operation, and is now perfectly well. Microscopical examination of a section of the growth showed finger like projections covered with cylindrical epithelium, recently formed connective tissue, and acini running down into the tissue.

Dr. Loomis said he would like the opinion of the members in regard to the nature of the growth, as the diagnosis in his opinion lay between papilloma, adenoma, or cylindrical-cell epithelioma.

DR. J. S. ELY thought it was a papilloma, and he suggested that it might have grown from the surface of the

ovary, the epithelium covering it being the analogue of the germ epithelium originally covering the ovum.

Dr. T. M. Prudden said that he would not hesitate to pronounce the tumor a papilloma, or more correctly a papillo-adenoma; and as to the origin of the growth, he thought it probable that the adenoma, instead of being confined in cysts, had worked its way through into the abdominal cavity, and therefore it was not necessarily derived from the germ epithelium. He had often seen this process in both ovaries, but usually not to the same extent.

The President concurred in the diagnosis of papillary adenoma, and said that he had seen one case in which the macroscopical and microscopical appearances were almost identical with those found in this specimen, and in which subsequently multiple growths appeared on the surface of the peritoneum. In this case there was considerable fibro-purulent exudation in the peritoneum, and a diagnosis had been made of tubercular peritonitis. As permanent drainage of the peritoneum had been established, it was possible that the peritonitis was the result of this drainage.

Dr. Prudden said that he had seen one such case in which so much had to be removed from the abdominal cavity that the operation was abandoned. No autopsy was allowed.

Pulmonary Tuberculosis.—Dr. H. P. Loomis also presented the lungs from a patient with pulmonary tuberculosis, who had been treated for three months with Koch's tuberculin.

C. D——, aged forty-seven, a laborer, was admitted to Bellevue Hospital on the 10th of last December, suffering from phthisis. Two years before, he had pneumonia, and it was fully two months before he completely recovered from this. With this exception, he was perfectly well up to three months before admission, when he was seized with a hemorrhage, followed by the ordinary symptoms of phthisis. Consolidation was confined to the apex of each lung, but the physical signs were more marked on the left side. An examination of the sputum showed one or two tubercle bacilli in each field. The case was considered a promising one for treatment with Koch's lymph, and the first injection was given on December 19th.

This was the first patient inoculated at Bellevue Hospital, and he received in all sixty-three injections of .001 c.c. each, the largest number given to any one patient. The injection was followed by an increase in all the physical signs, but after the first week the disease in the lungs apparently became quiescent and but few râles could be heard. For about two months there was a slow but steady improvement in the patient's general condition and he gained five pounds in weight, although the process in the lung seemed to remain about the same and the number of bacilli and the amount of sputum did not diminish. There were no fever reactions following the injections, the temperature ranging from 98.5° to 101° F. On February 25th, a cavity was first noticed at the left apex. On March 2d he caught a severe cold and immediately began to fail rapidly, so that in ten days he was unable to sit up in bed. Death occurred on March 15th.

The autopsy was made fourteen hours after death. Rigor mortis was present. The heart weighed half a pound; the valves appeared to be normal; there were a few atheromatous patches along the first portion of the aorta. The left lung was so adherent at the apex and over its posterior border, that it was impossible to separate it without lacerating the lung substance. The upper portion contained a number of inter-communicating cavities, the largest an inch and a half in diameter. On opening these cavities they were found to contain a reddish-brown grumous fluid, made up of broken tissues and red blood-corpuscles. The walls of the cavities were trabeculated and of a greenish necrotic color, and they were surrounded by a deeply pigmented zone of dense-looking tubercular tissue. The rest of the lung was of a deep-red color, and scattered through it were clusters of miliary tubercles surrounded by zones of intense congestion. These clusters were not aggregated, but separated by areas of apparently healthy tissue. All along the external border of the lung were cheesy tubercular masses, the size of a pea. The right lung showed in the lower portion of its upper lobe an area of slate-gray color, three inches in diameter, solid, with disseminated tubercles. It contained a number of cavities, none larger than a small pea. On the surface and in the substance of the lower lobe were a few clusters of miliary tubercles. The rest of the lung was emphysematous. The processes in the right lung appeared to be active and progressive; those in the left, quiescent and healing. There was apparently no recent eruption of miliary tubercles. The microscopical examination of a section through the walls of one of the cavities in the left lung showed tubercular material containing giant cells projecting into it. At the base of these projections were continuous areas of round cell infiltration, all the vessels near the cavity were intensely congested, and from some of them hemorrhages had occurred. The vessels removed from the cavity were not engorged. Areas of necrotic tissue were seen about the cavity. In all the sections examined the most striking change, aside from the excessive round-cell infiltration and intense hyperæmia, was the evidence everywhere of new connective-tissue formation. Very little old connective tissue was seen. Around the necrotic areas and in the alveolar walls the round cells were seen elongating into spindle cells, and new fibrous tissue was forming. The interlobular connective tissue was greatly increased by very recently formed fibrous tissue. Under the microscope the processes in the lungs appeared to be decidedly conservative; there was no extensive eruption of miliary tubercles found. The liver was of normal size and microscopical examination showed fatty infiltration and some cirrhosis. The intestines were normal with the exception of three tubercular ulcers, one the size of an almond and the others of a split pea. These were found in the lower portion of the ileum. No miliary tubercles could be detected in the wall of the intestines. The kidneys showed a moderate amount of chronic diffuse nephritis. The brain was not examined.

Hernia Simulating Abscess.— Dr. T. Halsted Myers presented an incarcerated omental hernia, protruding through the abdominal walls near the umbilicus, with a very long and narrow pedicle, which prevented impulse and made the tumor very movable. The surrounding integument was considerably indurated and there was a distinct inflammatory areola one inch in diameter about the mass, which thus closely simulated abscess.

Cystic Kidney.—The President presented a cystic kidney which had been accidentally found in the body of a man sixty years of age, who had died of acute lobar pneumonia, and without any history of renal disease. In a number of cases of congenital cysts of the kidney which he had seen the whole organ was involved, and the kidneys were of enormous size. One of these cases occurred in a woman who died just after childbirth, and who had been previous to this in apparently good health. In that case a most careful microscopical examination showed no normal renal tissue. In another case which had come under his observation the kidneys together weighed eighteen pounds, and the cysts were somewhat larger than in the present specimen, and existed in enormous numbers.

Dr. H. P. Loomis thought the specimen showed the cystic condition occasionally observed in very old persons. He thought it hardly probable that such a condition had existed since infancy without any symptoms referrible to the kidney.

Dr. Prudden considered the specimen one of congenital cyst of the kidney, for he was not aware of any such collection of cysts developing at a subsequent period. Although remarkable, it was nevertheless a fact that such

kidneys often functionate in a certain way for years. Dr. J. S. Ely had some time ago presented the kidneys of a pig, in which absolutely no normal renal tissue could be detected anywhere, and yet the animal had grown to a sufficient size to be slaughtered.

The President said that this reminded him of a cystic kidney which had been removed from a lamb at one of the slaughter houses, and had been brought to him for examination. It appeared to be identical with the congenital cystic kidneys seen in the human being.

The President presented the heart which had been removed from a patient who had been admitted to Bellevue Hospital for "destitution," and who was in such a feeble condition that no very thorough examination was made during the few hours which elapsed between the time of admission and death. Death apparently occurred from heart-failure. The autopsy showed a large thrombus in the apex of the left ventricle, and similar thrombi in the apex of the right ventricle and in the right auricular appendix. In the left side of the wall of the left ventricle, over a considerable area, the muscular substance was almost entirely replaced by dense fibrous connective tissue. In the right side of the wall of the left ventricle, in the interventricular septum, and involving a large part of the anterior wall of the left ventricle, was an infarction of the muscle. The muscular walls, for one-half or more of their thickness, had undergone coagulation necrosis, and the right coronary artery, just at its origin, was almost completely obliterated. In the smaller branches of the coronary artery were small thrombi. Strangely enough, there was not much change in the aorta or in its smaller branches. The extensive changes in the ventricular wall were evidently not of recent origin.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NEW UNIVERSITY FOR LONDON—MR. WILLIAM ANDERSON ON CONTRACTIONS OF THE PALMAR FASCIA—THE CENSUS RETURNS FOR ENGLAND AND WALES—THE LONDON WATER SUPPLY—ANOTHER LUNACY BILL.

London, July 18, 1891.

The Albert University for London bids fair to soon become an accomplished fact. On Monday last the committee of the Privy Council delivered judgment, in which they practically affirmed the petition of the petitioning colleges. The new university is to be styled "The Albert University" or "The Albert Metropolitan University," but the word "London" is not to be used in the title as likely to lead to confusion between the new university and the existing university in London. The claim of the Royal Colleges of Physicians and Surgeons to control the medical examinations is disallowed and the number of representatives from the Royal Colleges and the medical schools reduced. Whether the Royal Colleges and the medical schools will consent to come into the new university on the terms proposed, remains to be seen. They have stoutly maintained their claim to more extensive representation and control, but probably they will be wise enough not to persist in standing aloof because they cannot obtain all they wish. Honorary degrees are not to be conferred in the Faculty of Medicine, nor are any degrees in medicine to be conferred, except on candidates already in possession of a qualification to practise entitling them to be registered under the medical acts. A faculty of law is to be established. Only those candidates will be admitted to the examinations of the new university who have spent a period of at least two years in study in the colleges of the new university.

In his recent lectures at the College of Surgeons, on "Contractions of the Fingers and Toes," Mr. William Anderson discussed the subject of contraction of the palmar fascia. He concluded that this term had been used to describe two forms of disease. One of these was of traumatic origin and due to common inflammatory changes in the integumental and fascial structures. It occurred at all ages. The other variety was almost confined to middle and advanced life and unassociated with obvious traumatism. This condition—true "Dupuytren's contraction"—was not, strictly speaking, a contraction of the palmar fascia, but consisted of a chronic inflammatory hyperplasia, which commenced in the subcutaneous connective-tissue and involved secondarily the palmar fascia and the deep fibres of the corium. There was a tendency to multiplicity of lesion. The morbid bands were for the most part formed at the expense of the normal tissues. This form did not appear to be connected primarily with pressure or friction of the palm by tools or other objects employed in manual occupations, but was probably caused by a specific infective agent which effected its entrance through epidermic lesions made by the finger-nails or otherwise. It occurred in all classes, was more common in men than in women, tended to progress slowly through a long course of years, and to return after operation. The disease was, he believed, connected with a special diathesis, inherited or acquired, which could not yet be expressed in any known terms; but neither gout, rheumatism, rheumatoid arthritis, nor any other of the ordinary constitutional ailments had been shown to have any causative relation to the disease. The disorder appeared to be almost, if not quite, unknown in certain parts of the East, as in India and Japan.

The (preliminary) census report shows that the population of England and Wales was 29,001,018 on April 6th last. This was 703,350 less than it would have been had the previous rate of increase been maintained during the decennial period, 1881 to 1891. An error has in consequence been made in calculating the recent annual death-rates. This, however, is not very large. The death-rate for 1890 was estimated as 19.2 per thousand persons living. We now find that the number of persons living was over-estimated. The true death-rate was consequently 19.6 per thousand, but even this somewhat larger figure compares favorably with the mortality statistics of other European countries. An interesting point brought out by the census returns is that the growth of the towns at the expense of the rural districts appears to be somewhat checked. The result of the "city day census," taken on April 27th, shows that 301,383 persons were engaged on the city (an area of about a square mile) on that day—an increase of 40,320 over the number given by the similar census taken ten years ago.

The Committee of the House of Commons, which was appointed to consider the London Water bills, has recommended that the London County Council should be empowered to inquire into the whole question, and, if necessary, to bring in a bill to constitute itself a responsible water authority to purchase the undertakings of the water companies. Provision is also made for utilizing fresh sources of supply.

That our Lunacy law is still unsettled is shown by the fact that the Lord Chancellor has thought it desirable to bring forward a new lunacy bill amending the bill passed a short time since.

FLOATING HOSPITALS FOR SURGICAL OPERATIONS.

To the Editor of the Medical Record.

Sir: In these days of antiseptic surgery, the aim of the surgeon is to destroy all germs, so that no suppuration can occur in his wound. If he succeeds, other things being equal, his operation is a success. Now, it has occurred to me whether it would not be better to select a locality for operation where germs do not exist; where there would be no necessity for their destruction because

of their non-existence. We have been informed that in mid-ocean disease germs are very few, if not altogether absent, in the atmosphere. Following up this thought, it has suggested itself that a vessel, anchored ten miles out at sea, might offer the most favorable locality for surgical operations. There would be many drawbacks to such an idea; hence, from this ideal proposition we would deduce the practical idea that sea-shore localities, because of their comparative exemption from disease germs, would offer a locality most favorable for the performance of surgical operations.

JOSEPH F. EDWARDS, M.D.

147 S. ILLINOIS AVENUE, ATLANTIC CITY, N. J.

NERVE-FORCE, OR NEURICITY (?).

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The MEDICAL RECORD of July 18, 1891, takes to task the *Annals of Hygiene* and the *Lancet* for their explanations of the loss and gain of thrift by two persons who sleep together, and is especially severe on the use of the expressions "eliminate nerve-force" and "absorb nerve-force."

Why are these terms not as applicable to nerve-force as to heat? The former is no more "occult" than the latter before it becomes sensible from a state of latency. It is true that the laws which govern the one are not so well understood as those which regulate the other, because neurology is comparatively a modern science, and is just beginning to take its merited position abreast of the other sciences.

Electricity is evolved by the friction of amber (electron), and is named from that circumstance; why may not nerve-force be evolved by friction or irritation of nerve (neuron), and be called neuricity? Electricity is also evolved by chemical action; why may not neuricity be evolved by chemical action, the breaking up and making up of the compounds in the protoplasm of tissue-cells, during the processes of metabolism?

While neuricity is not identical with electricity, heat, or magnetism, and is not subject to the same laws, yet, in my opinion, it is a fluid force and a correlation of the natural forces. It is no great distortion of facts nor violation of reason to suppose that it may be absorbed or eliminated, accumulated or conducted, and by other media than the nerves.

In discussing reflex action, it is usual to say the peripheral end of the nerve is irritated, or a body impinges upon it. The "irritation," or "impulse," is conducted to the centre, and thence reflected. To my mind, the idea contained in the expression to conduct or reflect an irritation, or impulse, is of the "most fantastic and unsubstantial character," and hard to comprehend—indeed, absurd. How much simpler the thought that neuricity is evolved by irritation or impingement, flashes along the afferent fibre to the centre, and thence along the efferent to an organ or tissue.

There is no just reason why neuricity may not pass from one person to another, as electricity from cloud to cloud or the earth, when one is in the positive and the other in the negative condition.

"How is it that children thrive, that kittens grow, and that the average duration of life of the married is longer than that of the single?" Because of the similarity of the nervous states of children of the same family and kittens of the same litter. An equilibrium is early attained between the different states of nervous force in man and wife.

G. W. DRAKE, M.D.

CHATTANOOGA, TENN., July 21, 1891.

Decreasing Death-rate of Phthisis.—Thanks to new sanitary measures in England, there has been a diminution of more than thirty per cent. in the death-rate from consumption since 1861.

New Instruments.

A NEW FORCEPS FOR ADENOID GROWTHS.

BY R. C. HODGES, M.D.,

GALVESTON, TEXAS.

THE adenoid forceps ordinarily employed are frequently a source of danger to the uvula and soft palate, as the crossed or scissors action is apt to pinch or cut. In operating on these adenoid growths in the vault of the pharynx, very often one is obliged to dispense with a palate retractor. This is most frequently the case in operating on children.

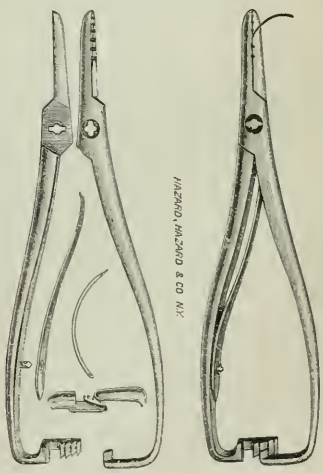
To avoid injuring, and at the same time to admit of lifting and retracting the palate, I have devised this forceps. The spreading of the blades enables the surgeon to cut freely and avoid the uvula. Another advantage is the large cutting surface. I have found this instrument very useful and practical, and believe that it possesses all the advantages of other forceps and is superior to all of them in the points I have mentioned. The instrument was made for me by E. B. Meyrowitz, New York.

AN IMPROVED NEEDLE-HOLDER.

BY DIXI CROSBY, M.D.,

NEW YORK.

IN trying to select a needle-holder which would combine strength, ease of manipulation, asepsis, and simplicity, I found that I was completely in the dark. Of the simpler



instruments most of them closed easily, but to open them required that exertion which would of necessity oblige the operator to use both hands, or, which to me is much worse, unsteadiness, and as a result not the fine work that should be done, especially in cosmetic surgery. After the experience of St. Patrick's day at Bellevue Hospital, I had the following described instrument built by Messrs. Hazard, Hazard & Co. It consists of simple forceps,

after the model of Professor McBurney, perfectly smooth and polished, with the French lock and the catch at the tail-piece. The instrument being closed on the needle, it is held by the notches as shown in the cut. To open it but requires an additional pressure, thus allowing the muscles of the hand the greatest advantage in action, and therefore securing to the operator the double advantage of steadiness and perfect control. At the suggestion of Professor Samuel Alexander, artery forceps of the same general model are being made.

One feels, in introducing a new or modified instrument now, as if he might be carrying coals to Newcastle, but with the hope that it may prove to the profession as convenient as it has to me, I offer it; with but the wish that it may add even a drop in the vast ocean of means at the command of the modern surgeon.

The Congress of American Physicians and Surgeons. - Circular No. I., dated Washington, June 24, 1891, reads as follows: The Committee of Arrangements takes great pleasure in announcing to the members and invited guests that the arrangements are sufficiently advanced to assure the success of the second triennial session of the Congress of American Physicians and Surgeons, which will be held in this city during the 22d, 23d, 24th, and 25th of September, 1891. A number of distinguished physicians and surgeons from abroad have accepted the invitation to attend, among whom may be named Mr. Thomas Bryant, Mr. B. E. Broadhurst, Mr. A. E. Durham, Mr. Reginald Harrison, Surgeon General Sir W. E. McKennin, Mr. U. Pritchard, Mr. F. Treves, Sir William MacCormac, Dr. James G. Glover, and Dr. William M. Ord, of London, England; Dr. McCall Anderson and Dr. W. T. Gairdner, of Glasgow; Mr. E. H. Bennett and Professor J. J. Cunningham, of Dublin; Professor John Chiene and Dr. J. Battey Tuke, of Edinburgh; Professor H. Krause and Dr. F. Beeby, of Berlin; Professor Curschmann, of Leipsic; Professor Hoffa, of Würzburg; Professor Kuhne, of Heidelberg; M. Emil Juval, M. E. Landolt, and Dr. Pozzi, of Paris; Dr. A. Mosso, of Turin; Dr. von Mozengeil, of Bonn; Dr. Lowenber, of Paris; and Dr. Rafail Lavista, of Mexico. The sessions of the congress will be held in the main hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue, from 3 to 6 P.M., daily. The president's address will be delivered in the lecture hall of the National Museum, Wednesday, September 23d, at 8 P.M., followed by the reception of the president, from 9.30 till 12. Order of executive committee. The Army Medical Museum will be open the same evening. The sessions of the societies will be held according to the programmes of each, respectively, in the places as follows: American Surgical Association, main hall, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; Association of American Physicians, hall No. 1, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; American Climatological Association, hall No. 2, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; American Gynæcological Society, lecture hall, Columbian University, 15th and H Streets, N. W.; American Laryngological Association, parlor A, Arlington Hotel; American Neurological Association, parlors 182 and 183, Arlington Hotel; American Orthopædic Association, new reception-room, Arlington Hotel; American Otological Society, ladies' parlor, No. 1, Arlington Hotel; American Ophthalmological Society, ladies' parlor, No. 2, Arlington Hotel; American Physiological Society, parlor 181, Arlington Hotel. The officers of the American Dermatological Association and the American Association of Andrology and Syphilology have made their arrangements with the Shoreham for places of meeting. Office of registration, parlors 1 and 2, Arlington Hotel. From this office the mail of members and guests will be distributed, and the city residence of each member or guest can be ascertained. The Association of American Anatomists will meet in this city during the sessions of the congress, and will occupy hall No. 3, Grand Army Building. The American Pædiatric Society will meet here September 23d and 24th, in the lecture hall of Columbian University, 15th and H Streets, N. W.

The congress will be composed of the members of the constituent societies and invited guests. A registration fee of five dollars will be required of every member of the constituent societies who may register; invited guests will not pay the fee. Order of executive committee. Participating societies can "accredit visitors to the congress, who shall pay the registration fee, but shall not be privileged to participate in the deliberations of the congress." Order of executive committee. A copy of the transactions of the congress will be sent to each person who may register. Only those who may register, invited guests, and ladies accompanying them, will be admitted to the reception of the president. Secretaries of constituent societies are requested to supply this committee with the names and addresses of "accredited visitors." The evenings of Tuesday, September 22d, and Thursday, September 24th, are left to the societies. Members of the American Surgical Association and of the Association of American Physicians will conjointly entertain their foreign guests at dinner at the Arlington Hotel, Thursday, September 24th, at 8 P.M. The American Gynæcological Society has also arranged for a dinner at the Arlington Hotel, Thursday evening, September 24th. The American Pædiatric Society will give a dinner September 24th. Other societies that intend to entertain their foreign guests are requested to communicate with this committee. Arrangements are in progress to secure reduction of railway fares. As soon as completed, the information will be communicated to each member and "accredited visitor." The Arlington Hotel offers accommodations at the rate of four dollars a day, and the Hotel Arno offers rates "on the American plan at three and four dollars a day, on the European plan at one dollar a day. Exclu-

sive use of bath one dollar extra." A blank certificate of registration will be sent to each member and "accredited visitor." The committee requests each person receiving such certificate to fill the blanks and return it, with the fee, to Dr. John S. Billings, treasurer of the congress. The American Pomological Society, and perhaps other societies, will meet in this city September 22d–25th. The committee therefore suggest to the members an early arrangement for hotel accommodations. Inquiries relating to railway fares must be addressed to Dr. S. S. Adams, 1632 K Street. A complete roster of membership of the congress has been prepared, with post-office address and society to which each member belongs. The committee will take pleasure in answering any inquiry relating to the local arrangements of the congress.

Signed, Samuel C. Busey, M.D., *Chairman*, 1545 I Street, N. W.; John S. Billings, M.D., Army Medical Museum; W. W. Johnston, M.D., 1603 K Street, N. W.; R. T. Edes, M.D., 1214 18th Street, N. W.; S. O. Richey, M.D., 732 17th Street, N. W.; J. Taber Johnson, M.D., 1728 K Street, N. W.; I. E. Atkinson, M.D., 605 Cathedral Street, Baltimore; C. F. Bevan, M.D., 807 Cathedral Street, Baltimore; Samuel Johnson, M.D., 204 Monument Street, Baltimore; Samuel Theobald, M.D., 304 Monument Street, Baltimore; H. Newell Martin, M.D., Johns Hopkins Hospital, Baltimore; De Forest Willard, M.D., 1818 Chestnut Street, Philadelphia.

The Abuse of Morphia in Paris.—The improper use of morphia subcutaneously is said to be extending very rapidly in Paris, with deplorable results, both mentally and physically, to the unhappy victims of the seductive habit. To meet the demand of the morphiamaniacs certain speculators have recently opened two establishments, to which people can go to have their craving after the poison gratified—the one for men, the other for women. They are not clandestine houses; the police are quite aware of their existence, and everything is decently and properly conducted at them. The drawing-rooms in which visitors are received are luxuriously furnished, and provided with books, newspapers, etc., for those who care for them. The price charged for the first injection of morphia is five francs, succeeding ones being half that price. A journalist who visited these establishments says the majority of the visitors were young men and young and pretty women.

Pathology of Grief.—That severe mental distress or fright sometimes produces physical disease, and occasionally even death, is an admitted fact, although the way in which it acts has hitherto been but little studied. In order in some measure to supply the deficiency in our knowledge regarding this matter, Dr. G. Bassi has recently made a number of observations on animals which apparently died in consequence of capture. Birds, moles, and a dog which had succumbed to conditions believed by Dr. Bassi to resemble those known among human beings as acute nostalgia and "a broken heart," were examined post mortem. Generally there was hyperæmia, sometimes associated with capillary hemorrhages of the abdominal organs, more especially of the liver, also fatty and granular degeneration of their elements, and sometimes bile was found in the stomach with or without a catarrhal condition. The clinical symptoms were at first those of excitement, especially in the birds, these being followed by depression and persistent anorexia. The theory suggested by Dr. Bassi is that the nervous disturbance interferes with the due nutrition of the tissues in such a way as to give rise to the formation of toxic substances—probably ptomaïnes—which then set up acute degeneration of the parenchymatous elements similar to that which occurs in consequence of the action of certain poisonous substances, such as phosphorus, or to that met with in some infectious diseases. In support of this view, he points out that Schule has found parenchymatous degeneration in persons dead from acute delirium, and that Zenker found hemorrhages in the pancreas in persons who had died suddenly. He refers also to some well-known facts concerning negroes in a state of slavery, and to the occasional occurrence of jaundice after fright. He hopes that these hints may induce medical officers of prisons and others to study both clinically and anatomically this by no means uninteresting or unimportant subject. *Lancet.*

Are Improving.—"The social relations among physicians are constantly improving," said a well-known Missouri doctor. "I can recall the time when doctors were extremely jealous, and even at their conventions would show a strong disposition to quarrel."

"Yes, that's a fact," answered a doctor who stood near. "Take our last convention, for instance. But two of the men that were shot died from the effect."

"Only one," said the first doctor.

"No, two."

"I ought to know. I was there."

"So was I."

"Then you ought to know what you are talking about."

"I do."

"You don't."

"You are a butcher."

"You are a liar."

A lawyer came up and separated them.—*Western Medical Reporter.*

The Temperature of the House in Winter.—We have lately read a very interesting article in one of the daily newspapers in regard to "Our Indoor Climate." The author is very critical of Americans for having so much artificial heating in our houses, but we think he has overrated the dangers from that source. The chief danger in New York City, from Christmas until April, is not from too warm houses, but from too cold ones, and those in which the temperature varies very much. We can get on out-of-doors with exercise and overcoats and sealskins; but inside the temperature ought to be kept up to 70° F. for most people, and for some old people in hospitals, 73° F. to 75° F. is not out of the way. The English are the great apostles for being uncomfortable inside their houses. The result there is seen in the great prevalence of rheumatism and also of aural diseases. It is very difficult to get warm in London or Paris in the winter. And we do not believe it ever does anybody any good to be just the other side of being warm. A man is as uncomfortable at 40° F. as he is at 20° F. It is possible that New Yorkers are a little careless in varying the heat in their houses, but not in keeping them too warm, we think. To keep warm is very often to keep well.—*The Post-Graduate.*

Ether-drinking in Ireland.—A parliamentary committee recently reported that the use of ether for drinking was quite common in South Derry and a portion of Tyrone, but not, as has been stated, in other portions of Ireland. The ether used is generally impure, and is made from methylated spirit. The character of the drunkenness is much the same as with whiskey, but it is more rapid in its action, while, as the after-effects are not so disagreeable, a person may get drunk two or three times in the day at very slight cost. In order to combat the habit it has been determined to declare the drug a poison, and so bring its sale under the restrictions of the Poisons Act.

An Early Sign of Whooping-cough.—Dr. Huguin, writing in *l'Union Médicale du Nord-Est* for May, 1891, states that he has observed several cases of pertussis in which photophobia with dilatation of the pupils was a prominent symptom in the early stage, while as yet the cough was only catarrhal in character. Conjunctivitis is not infrequently observed in the catarrhal stage of this affection, but the writer says that he has never seen dilatation of the pupil and photophobia, unaccompanied by conjunctival inflammation, mentioned among the precocious symptoms of whooping cough.

ON THE CHARACTER AND TYPES OF PELVIC INFLAMMATIONS IN THE FEMALE.

OBSERVATIONS BASED UPON A PERSONAL ANALYSIS OF THREE HUNDRED ACUTE CASES.[1]

BY HENRY S. STARK, A.M., M.D.,

NEW YORK.

My remarks upon the subject of pelvic inflammations in the female are based not so much upon the present literature of the subject as upon a personal analysis of over three hundred acute cases, most of which have come under my observation within a few years in connection with my service at the Mount Sinai Hospital, New York. These cases illustrated the many and varied phenomena of the affections, their complications and sequelæ, and have afforded me an ample opportunity of appreciating their immediate and remoter consequences. Further, this comparatively large material has furnished me with data which, on the one hand, completely harmonized with the deduction of others, and, on the other hand, led me to draw conclusions differing in several respects from those of certain other observers, and which, as I feel in a measure equipped, I shall hope to incorporate in these remarks without pretending to give a precise description of typical cases, which only weary the reader and occupy space.

From time immemorial these inflammations have attracted such widespread attention, and have occasioned such a voluminous literature, that it would be reasonable to suppose that in our own day there could be no possible conjectures in regard to their origin, nature, and causation; yet there are problems connected with the subject bearing on these points which have baffled the most thoughtful observers, and are consequently no nearer solution, even in this progressive age of medical thought and enlightenment, than they were when this subject first engaged the minds of medical men.

The great Ricord once described heaven as a place where he would not expect to meet with cases of gleet; reasoning by analogy the gynecologist's idea of Paradise would be some place where he would no longer encounter cases of pelvic inflammation, for certain it is that these fell disorders constitute so large a proportion of diseases for which he is consulted, that if by some special dispensation of Providence they were no longer to prey upon our child-bearing humanity, it might well be said that, like Othello, the gynecologist's occupation would be gone. There are not many women who, during their menstrual activity, have not been the victims of some pelvic inflammation of greater or lesser intensity. The fact that an attack may be so slight in character that the local phenomena of the affection may escape detection, cannot fail to be recognized as strong corroborative evidence that the attack may be overlooked or detected according as the practitioner is ill- or well-informed on this particular theme. Thus every summer when the diarrhœas of gastro-intestinal diseases are prevalent, a number of cases of pelvic inflammations which are ushered in or attended with diarrhœic movements are misinterpreted as acute gastritis, enteritis, or colitis, as the case may be, and may run their course unrecognized, or remain unrecognized until, at an advanced period of their progress, an examination reveals the presence of a pelvic exudation. Thus also have I seen a number of afebrile cases of pelvic inflammation, attended only with constipation and vague abdominal pains, in which the true significance of the clinical picture was also misinterpreted by physicians in whose hands these cases had originally fallen. Apropos, I distinctly recall the case of a girl, nineteen years of age, suffering from diarrhœa, indefinite abdominal pains, and the symptoms of a high temperature, who had been regularly visited for two weeks by her physician, and had been treated by him for typhoid fever. Two or three days before her death I first saw her, and on vaginal examination mapped out an exudation involving the whole pelvic roof. Questioning the physician, I elicited the fact that a vaginal examination had not been made, as he had considered it "a clear case of typhoid fever."

The term "pelvic inflammation" would properly include an inflammation of any organ or tissue within the pelvic cavity, but throughout this paper the term will be employed collectively to include a pelvic peritonitis or a pelvic cellulitis in preference to any other nomenclature, and with the conviction (since the two varieties generally coexist, the one or the other preceding and predominating) that there are no constantly recurring pathognomonic features peculiar to each which would enable the practitioner to make the differential diagnosis in all cases with positiveness. In this connection you vividly recall the schematic representation in parallel columns of the differential diagnosis found in most text-books. This table charitably informs the reader that if the patient's one leg be drawn up he is dealing with a cellulitis, if both legs be drawn up the indications are those of a peritonitis; that in cellulitis the tongue is coated, in peritonitis it is clean and red; further, that in cellulitis the uterus can be moved without excessive pain, in peritonitis it cannot; then follows a conglomeration of equally instructive data, enumerated in the same confidential and categorical strain. Equipped with this carefully acquired information, the average medical student leaves his college believing himself prepared to cope with the exigencies of his female *clientele*, and applies his lore promiscuously for weal or for woe. This is neither an overdrawn nor an imaginary picture, but a plain statement of the truth, as many of the younger generation of physicians could substantiate. What other object authors who recommend such schedules can have than to accommodate enterprising quiz masters, or to mislead timid students, I fail to understand; for surely their own vast experience must have taught them that the differential diagnosis cannot be drawn on any such hard-and-fast lines.

A moment's consideration of the nature and relation of the anatomical parts involved in these inflammations, and of the similarity of their local and constitutional effects, will convince the most sanguine that any claim to make a differential diagnosis, with any degree of certainty, in all or even most cases, and to locate precisely the seat and extent of the inflammatory process, is one that borders on the chimerical, and must be considered *cum grano salis* even when emanating from specialists. To me it has always been a matter of surprise to observe with what ease and contentment some physicians will diagnosticate the one or the other inflammation, and merely on the preponderance of a certain train of subjective symptoms,

[1] Read at the May meeting of the Alumni Association of the Mount Sinai Hospital.

or from the amount of awe with which the gravity of individual cases inspires them.

In that set of cases in which the seat of inflammation involves the broad ligaments, it can hardly be conceived that one species of inflammation could occur without subsequently giving rise to the other from extension by continuity or contiguity of surfaces, nor would it be reasonable to suppose that the combination of the two varieties of inflammation in these latter cases would occasion any differeuce in the complex of symptoms or in the sequence of events from that produced by either inflammation, if it were to occur singly; for the anatomical elements of the broad ligaments, viz., peritoneum and connective tissue, are so intimately blended and so luxuriously supplied with blood and lymph-vessels that one cannot conceive a more perfect mechanism for the reception, transmission, and propagation of infectious matter than this intricate partition stretched across the pelvic cavity. As well might one believe that a pneumonitis would occur without its complicating pleuritis, as to imagine that within the broad ligaments one species of inflammation would occur without its correlative species. In the utero-sacral and utero-vesical regions the anatomical conditions, with respect to the distribution and relation of serous membrane and connective tissue, are similar to those in the broad ligaments, and consequently the liability to a combination of the two inflammations is as great. Since, then, it may be fairly claimed that the two varieties are reciprocally and inseparably related, it is of paramount importance that the fact become properly recognized by associating with these inflammations a more appropriate nomenclature than is the custom at the present day. The terms pelvic peritonitis and pelvic cellulitis, or perimetritis and parametritis, are inadequate, as they indicate a distinction which exists theoretically, but not clinically. Terms should be coined which would tersely express the duplicate and compound nature of these inflammations, and which would, at the same time, convey the idea of the locality of lesion.

It is not claimed that all cases present these drawbacks toward differentiating between the two varieties to the same extent; on the contrary, there are many cases in which the differentiation is made readily enough from the locality of the exudation; a bulging, for instance, on the left side of the v ginal fornix may be safely interpreted as due to a primary and predominating cellulitis, while an exudation in Douglas's pouch most frequently points to a primary and predominating peritonitis. But the point intended to be emphasized is, that since the clinical picture and the pathological products and residues are so self-same, a thorough differentiation cannot be made with mathematical precision at the bedside, but rather in the post-mortem room, and that therefore any wholesale attempts to make a close clinical discrimination should be gainsaid, as they would be based upon fancy rather than upon sound judgment. If, then, this state of affairs is a hindrance to the specialist, it presses with double weight upon the general practitioner, for he most frequently sees these cases in their acuter stages.

While alluding to the inadvisability and difficulty of discriminating between the inflammations affecting the pelvic peritoneum and connective tissue, I would further call your attention to an allied periuterine condition of comparatively frequent occurrence, yet rarely recognized, a condition mentioned in few text books, and only treated of in outline at that, namely, acute and chronic inflammation of the periuterine lymphatic ganglia and vessels, the so called pelvic lymphadenitis and lymphangitis. That there is such a distinct pathological entity, manifesting itself by distinctly recognizable physical signs, and unaccompanied by kindred secondary inflammations, in other words, apparently idiopathic, has been abundantly demonstrated by post-mortem examinations and clinical observations.

The first to allude to the pathological significance of this lesion, both in puerperal and non-puerperal states, was Championnère,[1] in 1870 and 1875 respectively. Next Leopold,[2] of Leipzig, minutely described the uterine lymphatics and demonstrated the great susceptibility of this vascular system to microbic infection. To him the profession is indebted for the most complete knowledge we possess of the uterine lymphatic system. He considered the mucous membrane of the uterus as a vast lymphatic surface, dotted with numberless gaping orifices or portals, through which septic matter could find a ready ingress and communication with the lymph spaces of the pelvic peritoneum. In this country, Carreau[3] was the first to observe and report cases of pelvic adenitis; but to Dr Paul F. Mundé[4] is due the credit of having first brought the subject prominently before the American reader in an elaborate article, in which the signs and symptoms are graphically described, together with the report of six cases which came under his observation in rapid succession. For the most complete description of this lesion, I would refer the reader to the work of the French writer, Courty.[5]

The fact that no mention is made of this lesion in the more familiar text books, and consequently that this disease has not been credited as yet with any particular status in our gynecological nosology, by no means challenges its importance or disproves its identity, for it is certainly within the pale of belief that the pelvic lymphatic may become inflamed under the same exciting causes as the lymphatic system elsewhere. Indeed there are plausible reasons, depending on autopsical evidence, for believing that the pelvic lymph-vessels and glands are frequently the very nidus of infection, from which in turn septic processes spread in all directions.

This scanty allusion to the subject of pelvic lymphadenitis will, it is hoped, make it appear that these inflammations are a much more frequent incidence than one would be led to believe, and that many cases of so-called pelvic peritonitis and pelvic cellulitis are merely unrecognized instances of it. The knowledge that inflammations and other affections of the pelvic lymphatics will determine a symptomatic aggregate tolerably well-defined, yet quite analogous to that produced by other pelvic inflammations, seems to offer a satisfactory explanation for our extreme liability to overlook the affections of the pelvic glands; for pelvic lymphadenitis, lymphangitis, peritonitis, and cellulitis, especially in their chronic forms, simulate each other so closely, subjectively and objectively, that only those who are aware of this particular lesion, and are constantly on the look-out for its characteristic features, will occasionally find their patience rewarded by the detection of typical cases.

Still another species of pelvic inflammation, which, though of rare occurrence, occasionally makes itself manifest, and in such a manner as to simulate pelvic peritonitis or cellulitis, is pelvic periphlebitis. There being an abundance of venous plexuses within the pelvis, it is to be assumed that an inflammation might, from time to time, arise among them. Naturally enough one must possess the *tactus eruditus* to a marked degree to be enabled to detect this condition, for whenever it does occur, it gives rise to no very definite symptoms, nor is it attended with any characteristic physical signs; in point of fact, it usually remains unrecognized until after the abdomen has been opened. It is, however, reasonable to suppose that those women are predisposed to this condition who suffer from constipation and a sluggish venous circulation, as manifested by the constant presence of hæmorrhoids and varicose veins of the legs. Given a case of pelvic inflammation, accompanied with the above

phenomena, if after the acute inflammation has subsided a vaginal examination reveals neither an exudation nor any circumscribed swelling within the pelvis, periphlebitis ought certainly to be thought of. A condition which, it appears to me, highly favors, or may determine, a pelvic periphlebitis, is puerperal crural phlebitis, for it is well known that venous thrombi have often been demonstrated in the uterine and hypogastric veins of patients who suffered from this puerperal complication, which fact would make it appear that these two varieties of phlebitis are reciprocally related at times. As regards the symptomatology of phlegmasia dolens, it is equally well known that the pains attending it are at times preceded or followed by pains in the region of the pelvis, which fact would likewise arouse suspicion of the presence of a complicating or primary pelvic phlebitis.

There are those who believe that pelvic phlebitis plays a most important rôle in the causation of pelvic cellulitis and peritonitis; that is to say, that the inflammation of the veins on the one hand, and the cellular or peritoneal inflammation on the other, stand in a reciprocal relation of cause and effect. This correlation, it would appear, ought to obtain more frequently in the puerperal than in the non-puerperal state, for it is well known that in puerperal pyæmia, for instance, the portal of infection is through the veins; consequently in this variety of puerperal infection the phlebitis would be primary, while in non-puerperal cellulitis it would be apt to be consecutive, since the *materies morbi* would be likely to enter the general circulation through the lymphatics. This fact was pointed out and verified successively by Trousseau, Courty, and our own Emmet, the latter expressing himself as follows, quoting from his text-book: "I am deeply impressed with the belief that future observation will establish the fact that the point of origin of inflammations in the pelvic cellular tissue is in the veins."

Autopsical evidence has abundantly demonstrated the fact that pelvic phlebitis is a frequent complication of pelvic cellulitis. Courty believed that the criterion available to determine the order of precedence was the presence or absence of obstructing vein-clots. If the autopsy demonstrated their presence, then the phlebitis was the cause of the cellulitis; when, however, venous clots were absent, while the tunics of the vein gave evidence of being involved in the inflammatory process, then the phlebitis was secondary to the cellulitis.

I have intentionally directed attention to these different varieties of pelvic inflammations in order to make it apparent that cellulitis and peritonitis are not the only ones, and further, to establish the fact that a clinical differentiation is well-nigh impossible in many, or rather most, cases, or, at any rate, superfluous for purposes of treatment.

Acute inflammations of the pelvic peritoneum and connective tissue are often secondary to disease of the ovaries and tubes, particularly the latter; indeed, there are reasonable grounds for believing that in many cases the cellular or peritoneal inflammation is only the final link in a chain of inflammations beginning in the uterus or its appendages. My own experience has taught me to look upon those cases of pelvic inflammation which furnish a previous history of acute or chronic cervical or corporeal endometritus, as evidenced by the usual manifestations of these affections, as the very ones in which the pelvic inflammation is a coincidence originating under some strongly predisposing influence, as sepsis, traumatism, or violence, and caused by direct extension of the endometric inflammation into the tube and ovary; or else the pelvic inflammatory process resulted from an extension of the endometritis by means of the intermuscular connective tissue of the uterus, through it to the pelvic connective tissue and peritoneum, which it is prone to do from the intimate relationship existing between the tissues of the cervix and of the pelvis. The process of extension of an inflammation in the path of least resistance finds its analogue in inflammations of all other mucous membrane tracts—the respiratory, the intestinal, and the genito-urinary canals. In the case of the last the statement is particularly applicable, for it is well known that cystitis, for example, is rarely an idiopathic, but almost invariably a secondary, affection; just so within the pelvis, neither the peritoneum nor the connective tissue are inclined to idiopathic inflammatory processes, but become frequently affected by extension of structure, in which event the order of sequence would be about as follows: Either lacerated cervix, cervical endometritis, corporeal endometritis, salpingitis, ovaritis, pelvic inflammation; or else beginning with lacerated cervix, or an erosion of the cervix, or with an endometritis, thence interstitial metritis and pelvic inflammation. I can recall quite a number of cases which illustrate these latter observations, several of them of gonorrhœal origin, in which the inflammation could be traced from the external genitalia into the pelvis; others again, were due to the absorption of septic matter during parturition or during the puerperium; in fact, it appears to be the tendency of infectious matter not to remain localized, but to spread by means of communicating channels.

Recent clinical and pathological data render it more and more certain that circumuterine inflammations are frequently secondary to inflammations elsewhere in the genital tract. This view was expressed years ago by Duncan, and at the present day the correctness of the doctrine is being generally admitted by eminent gynecologists. Thus Winckel is of the opinion that lacerations of the cervix are frequently the initial pathological conditions necessary for the production of pelvic inflammations, a view which approaches certainty when we consider the gross anatomy of the cervix; for we recall that the neck of the uterus is richly supplied with blood- and lymph vessels which communicate with pelvic plexuses of the same; and secondly, that the tissue of the cervix communicates directly with that within the pelvis through the intermuscular connective tissue of the uterus. Thus it becomes apparent that whenever there is produced a solution of continuity on the cervix, there are exposed a number of gaping orifices of blood- and lymph-vessels which afford a ready ingress and shelter for all kinds of septic matter, and which provide a channel for its transmission to other tissues. This anatomical peculiarity of the cervix is not a matter of mere detail, but of the highest practical importance, as it reminds us of the risk attending lacerations, and teaches us to employ gentleness when manipulating the cervix.

The pathogenesis of these inflammations differs in no respect from that of inflammations of cellular and serous membranes elsewhere, except as far as may be modified by the particular locality. There are the same morbid inflammatory products derived from the usual sources, with the same tendency of the exudate to form adhesions with adjacent tissues. These bands of adhesions latterly contracting, cause displacement of the organs involved, with subsequent disturbances of their normal functions. There may result, after the subsidence of the acute attack, sterility, amenorrhœa, dysmenorrhœa, menorrhagia, metrorrhagia, or, if suppuration have taken place, the ovaries may be destroyed or undergo atrophy, or the tube may be involved and rendered impervious or dropsical. There are the same stages of the inflammation. First the period of congestion or engorgement, then of exudation, then an organization and moulding of the exudate to conform with the contour of the parts involved, then the period on the one hand of resolution and on the other of suppuration. If suppuration take place and there be no operative interference, the pus either burrows along the path of least resistance, in accordance with the laws of gravitation, until it finds a channel of evacuation, or else it becomes encapsulated by pyogenic membranes, forming a distinct cyst. In case resolution set in, the exudate disappears by absorption. The types of inflammations within the pelvis conform also with the types elsewhere, thus there may be a catarrhal, suppurative, gonorrhœal,

tubercular, or malignant variety. The order of frequency of these, as far as my personal observations are concerned, is as follows: Catarrhal, gonorrhœal, suppurative, tubercular, malignant. The catarrhal is probably the most frequently encountered, fully one half to three-quarters of all cases, as ordinarily met with in general practice, are of this variety. They result almost invariably from parturition, or abortion, or direct extension of an uterine, tubal, or ovarian inflammation into the pelvic, serous, or connective tissue. That gonorrhœa plays an important *rôle* in the causation of pelvic inflammations is now generally recognized by the profession. As early as 1872, Noeggerath pointed out the fact that, just as acute uterine blennorrhœa might result from acute urethral infection, so chronic blennorrhœa of the uterus and its appendages might frequently, and does frequently, result from latent or chronic male blennorrhœa. In the face of the mass of evidence that has accumulated up to the present day, based on clinical observation and experimental studies, this view can no longer be relegated to the realms of uncertainty, but must be accepted as truth, especially since the gonococci have been satisfactorily demonstrated in peritoneal exudations.[1]

Noeggerath distinguished three varieties of pelvic inflammations due to gonorrhœal infection; namely, acute perimetritis with or without parametritis; secondly, recurrent perimetritis; and thirdly, chronic perimetritis. To the first class belongs that set of cases who become attacked with pelvic inflammation soon after marriage, or who complain of vague abdominal pains during their first pregnancy, and are attacked with pelvic inflammation directly after parturition, despite a rigidly antiseptic accouchement. Such cases are common enough, some of them are misinterpreted as puerperal fever. In many of them, if the attending physician be sufficiently interested in the etiology, a history of pre-nuptial gonorrhœa could be elicited from the husband. The second variety is associated with pyosalpinx. In point of fact, there are some who believe that purulent salpingitis or ovaritis is invariably gonorrhœal in origin. The third variety is usually accompanied by flexion or version of the uterus, with consequent disturbances of its physiological functions, with adhesions, with tenderness in Douglas's pouch, and in very many cases with permanent sterility. It is not difficult to understand how a bilateral pelvic inflammatory process, whether resulting from gonorrhœal infection or from any other species of infection, should be followed almost invariably by sterility. In the case of gonorrhœal infection, the fructifying virtues of both spermatozoa and ova are destroyed, or else through mechanical interference these elements are prevented from coming in contact.

There is one point of distinction which the pelvic peritoneum enjoys, which is not common to serous membranes in other localities; namely, that inflammations of the pelvic peritoneum do not spread and involve the general peritoneum. This immunity, so to speak, is by no means in the natural order of events, for the peritoneum being a continuous membrane, it would be logical to suppose that an inflammation involving the lower folds would spread by continuity of surface to the upper ends. Yet this is rarely the case, and in all the many cases which have come under my observation I can recall only a few in which a general peritonitis followed a pelvic peritonitis, and even these cases would come more properly under the category of acute general sepţicæmia of puerperal origin rather than of pelvic peritonitis so called. When we take into consideration the free communication of the peritoneum with the general lymphatic system, the readiness with which it receives and transmits infectious matter, the disposition of inflammations in general to propagate and extend, it becomes, indeed, a matter of surprise that general peritonitis is a not more frequent event in the history of pelvic peritonitis.

[1] Ceppi: Revue méd. de la Suisse, 1887.

Inflammations of the pelvic cellular tissue, like phlegmonous inflammations in different and distant parts of the body, are self-limiting in extent and duration; we may therefore conclude from analogy that there is no such affection, anatomically, as a chronic pelvic cellulitis *per se*. The acute inflammation, after a variable but comparatively short period, terminates either by resolution or by suppuration. If the latter, the phenomena cannot be considered as a chronic inflammation, but rather as one of its results; just as adhesions, cicatrices, displacements, subinvolution, or inflammatory residues may remain as sequelæ of the original inflammation. It is therefore necessary to discriminate between the chronic products of an inflammation and the inflammatory process itself. Thus chronic suppuration due to the pres ence of a badly drained abscess, a sinus, or a long, tortuous fistula, frequently enough complicates a pelvic cellulitis, but the train of symptoms that accompanied the cellulitis will long have disappeared, presuming the pus to have found a channel of evacuation; while the areolar tissue which was involved will have regained its normal histological state, except in those parts where the destructive suppurating or inflammatory process has permanently altered the anatomical elements.

Inflammations of the pelvic peritoneum, on the contrary, have, I believe, often a tendency to become chronic from the start. This would be quite analogous to what we know of the pathology of serous membranes in other parts of the body.

The well-recognized fact that women who have suffered from one attack of pelvic peritonitis are extremely liable to subsequent attacks upon exposure to the slightest predisposing influences, seems to speak for the existence in them of a latent chronic inflammatory process ever ready to break out in all its former virulence and intensity. This liability to exacerbations cannot properly be attributed to the inflammatory residues; for there are women who carry about them for years cicatrices, displacements, and adhesions of the uterus and its adnexa, that were occasioned by affections other than pelvic inflammations, and yet these same women perhaps have never suffered from any pelvic inflammation whatever. Further evidence of the persistence, or rather chronicity, of pelvic peritonitis is the fact that in some cases the attacks recur, with more or less intensity and regularity, during menstrual periods. Such cases are not uncommon. Moreover, these attacks occur without any appreciable exciting causes, which fact would go to show that there must be present a latent or dormant grade of chronic inflammation. It might be supposed that it would be an easy matter to determine this point by clinical observation, but in point of fact the determination is not so easy. In many of these cases the monthly exacerbations are not sufficiently severe to render it necessary for the patient to seek medical advice, consequently they are not under critical observation by any one physician from the beginning of the initial inflammation through all its phases and vicissitudes. The most reliable evidence would be that furnished from autopsies and physical examinations during life. Observers, generally, are at present availing themselves of these resources.

I have thus attempted to describe briefly the present views of the status of pelvic inflammations in the female. To summarize I would draw the following conclusions:

1. Idiopathic pelvic inflammation is a myth and a delusion, the inflammation is almost invariably secondary to uterine, tubal, or ovarian disease.

2. Most cases of non-puerperal pelvic inflammation, if not due to traumatism, are of gonorrhœal origin.

3. In the present imperfect state of our diagnostic resources the establishment of a differential diagnosis must be in many cases mere pedantry.

4. In the present imperfect state of our therapeutic resources the differential diagnosis is not of the very highest importance.

270 Seventh Street.

THE ETIOLOGY AND TREATMENT OF ATROPHIC RHINITIS.[1]

By JONATHAN WRIGHT, M.D.,

BROOKLYN, N. Y.

Atrophic rhinitis under its proper name, or under that of its principal symptom, ozæna, is a subject too extensively and thoroughly treated of in text-books and in general literature to make any complete review of it either instructive or interesting. It is, therefore, only my purpose here to record personal views upon some points concerning which there has been, and still is, considerable controversy and difference of opinion.

Ozæna being now generally discarded as a distinctive name of any pathological process, is regarded as the principal symptom of several; yet the ozæna which attends the formation and retention of crusts in the nasal fossa, affected by typical non-ulcerative atrophic rhinitis, is an odor perfectly distinct from that attending any other form of decomposition either in or outside the nose. Syphilitic ozæna, or the ozæna of carious intra-nasal bone, and the ozæna from a foreign body in the nose, are both distinct in character from it.

It has been stated that this odor is present where no atrophy exists (Mackenzie;[2] Gottstein[3]). These instances are of very great rarity, and as the interior of the nose, especially where hypertrophy is present, cannot be thoroughly inspected in all its parts even with the best illumination, it is impossible to exclude the existence of atrophied glands and an altered epithelium. Such cases are, I believe, the beginning of the change from hypertrophy to atrophy, and one or two such instances have come under my observation.

Rather more frequently we find atrophic rhinitis without either crusts or odor, especially in people beyond forty-five. It is impossible to say whether these cases have run their whole course without them, but although no such history is obtainable in some of the cases, it is probable that they were present in some degree at an earlier age. In other words, these are cases in which nature has cured the ozæna and left apparently unchanged the pathological process on which the symptom depended. The statement that the peculiar smell of ozæna may exist without the presence of retained secretions, should certainly be received with great reserve. Personally, I have never seen such a case, and I am inclined to believe those reported were cases in which crusts were hidden from view in the accessory cavities of the nose. Cases have been reported (I recall one) in which the crusts of ozæna existed only, or chiefly, in the antrum of Highmore. The intensity of the odor varies in different cases from almost nothing to a stench so offensive as to be unbearable.

Notwithstanding the fact that the disease sometimes occurs in persons of the very best general health and of irreproachable family history, it is more frequently seen in poor constitutions and in persons with a weak family record of health. The experience of other observers does not confirm the assertion of Voltolini,[4] that it occurs as frequently, or more so, in the rich than the poor. Heredity plays no *rôle* in the etiology of the disease. In one instance, however, I have seen it in three generations. In several instances I have seen it in sisters, once where both children were less than ten years of age. There is no proof, beyond such uncommon cases of coincidences, that the disease is contagious in the ordinary acceptance of the term. Voltolini[4] says: "In my experience the disease is a woman's disease. I have observed it almost exclusively in the female sex, in some very rare instances also in boys and men, and in these latter there was still a question if there was not something else at the bottom of it."

Massei,[1] on the other hand, says that "sex has not much influence on the development of ozæna," while Jurasz[2] shows that in his experience it is only two or three times as frequent in women as in men. In my own experience it is certainly a rarity in the male, unless depending upon some local malformation of the septum. This is in striking contrast to hypertrophic rhinitis, which is much more frequent in men than in women.

Atrophic rhinitis being most frequent in the female, and most frequently developing at the age of puberty, while it is rarely seen after the menopause in women, it is fair to conjecture that there is some unexplained influence exercised upon the course of the disease, at least as far as the ozæna goes, by the genital apparatus.

The ozæna is usually more offensive at the menstrual period than at other times. Exceptions to this are frequent, but not sufficiently so to invalidate the assertion. Nevertheless, it occurs at all ages. I have seen it in infancy and in old age. In the former, however, it must not be mistaken for the nasal lesions of hereditary syphilis. While atrophy may begin in adult life, ozæna rarely begins after thirty (Mackenzie).

Some years ago Zaufal advanced the theory that ozæna was due to congenital smallness of the turbinated bones causing an abnormal roominess of the nasal chambers; while Sauvage and Tillot (quoted by Massei), on the other hand, claimed that it was caused by a congenital narrowing of the nasal fossæ. These statements have rather an historical than a practical interest, as they have received little support from the large numbers of contributors to the literature of the subject. Clinically, we often see atrophy in one nostril associated with abnormal roominess of the fossæ, caused by extreme deviation of the septum to the other side. These cases can usually be promptly cured by correcting the deviation of the septum.

Michel and others have stated that many cases of atrophic rhinitis are caused by a suppurative inflammation of the accessory sinuses. It is true that these conditions may co-exist in rare instances, and it often happens that suppuration of these cavities is mistaken by careless and inexperienced observers for the ozæna of atrophic rhinitis. There is little evidence that either of these affections has any causative relation to the other.

It is generally agreed at present that syphilis, either congenital or acquired, has nothing to do with non ulcerative atrophic rhinitis, while struma, with which Stoerk connected the disease, has no definite meaning in modern pathology. It is, probable, however, that atrophic rhinitis may be congenital, as it is occasionally, though very rarely, seen in an advanced stage in young infants.

There is no connection between tuberculosis, either localized or general, and atrophic rhinitis, and it is my impression that phthisical patients do not furnish their quota of ozænas. The suggestion was lately advanced by Spencer Watson[3] that atrophic rhinitis is the analogue on a mucous surface of lupus erythematosus on the skin. Another London authority (Mr. Woakes[4]) explains its etiology by supposing it to be due to some pathological state of the vaso-motor nerves. These are certainly curious and interesting theories, but belong almost entirely to the realm of speculation, having no clinical or pathological proof. It is still a hotly debated question as to whether atrophic rhinitis is a disease by itself, commencing *de novo*, or whether it is the later stage of hypertrophy. Bosworth[5] claims that in the early stages, *i.e.*, usually in childhood, these cases suffer from suppurative rhinitis. As time goes on the elements of the mucous membrane become altered in structure, and atrophy, both of the investing and the glandular epithelium occurs, crusts form, and their contraction, as they dry on the sur-

face of the turbinated bones, exerts pressure which causes the extreme atrophy. This is certainly a very attractive and simple theory, and if the premises are once granted it appeals strongly to reason.

In my experience, and in that of many others, chronic purulent rhinitis is a rare affection, both in adults and in children, unless dependent upon syphilis, a foreign body, suppuration of the accessory cavities, or upon a marked general enfeeblement of body due to the presence of some chronic malady, such as tuberculosis in some of its many forms. The only clinical indication which would point to that origin of the disease, which I can recall, is that occasionally, in well-developed cases of atrophic rhinitis, a history can be obtained that the nasal secretion at first was abundant and came away freely. I remember a few cases of chronic purulent rhinitis in the adult; whether they went on to atrophy I am unable to say. Nevertheless, it seems highly probable that atrophy should follow such cases, but their great rarity in children fails to account for the comparative frequency of ozæna in adolescence.

The contracting pressure of the dried crusts will hardly explain the atrophy, because there must have been great and important alterations in the mucous membrane which produced this abnormal viscidity of the mucus, which prevented its flowing from the nose. That atrophy causes the crusts, and the crusts cause the atrophy, is not entirely satisfactory to the inquiring mind. Contrary to Bosworth's remark, that the epithelial structures are apt to be involved in pathological changes in the mucous membranes in youth, it is universally admitted that these changes—benign as well as malignant epithelial growths—belong at least to mature adult life. The tonsils are lymphoid, not epithelial structures. The tendency to atrophic changes in all tissues of the body belongs to late adult life, not to adolescence. Hypertrophy is most frequent before middle life, but also, at least in the nasal mucous membrane, after adolescence. It certainly, therefore, seems to me that the facts do not fit in with Dr. Bosworth's theory.

It is the belief of perhaps, the plurality of observers, that atrophic rhinitis is the latter stage of a pre-existing hypertrophy. While this is not an entirely satisfactory view, it seems to me to coincide better with clinical observation, and our knowledge of analogous pathological changes elsewhere, as in chronic inflammation of the internal organs. If it is true that atrophic rhinitis begins as such, the only analogy we have to it is the atrophy which follows nerve degeneration, a thought which may be of some comfort to Mr. Woakes.

Hypertrophic rhinitis, while not rare, is not a common affection in children. If we are to suppose that this, as well as other inflammations, simple catarrhal or suppurative, end in atrophy, we must acknowledge some unknown biological factor which makes that change very much more common about the time of puberty in the female.

In a few cases I have been able to notice this change from hypertrophy to atrophy. These two conditions may coexist in the same nostril, atrophy of the inferior and hypertrophy of the middle turbinated bone. The condition wrongly called by Woakes "necrosing ethmoiditis," is not infrequently observed in connection with atrophy of the inferior turbinated bone. A furrow traverses longitudinally the middle turbinated bone, dividing it into two halves. Pus is seen to exude from this furrow and from the ethmoid cells. There is, however, no carious bone. Occasionally advanced atrophy may be observed in one nostril, and marked hypertrophy in the other. I have yet to see a case in which one nostril is occluded by crusts and the other is secreting abundant fluid, muco-purulent matter.

It is impossible to deny that atrophy of the mucous membrane may begin *de novo* in rare cases. Almost everything is possible in pathological processes, at least our comprehension of the laws which govern them is too feeble to make us dogmatic about any of them. At present, rules and theories in medicine are for the slowly disappearing didactic lecturer, rather than for the clinical instructor.

A few years ago, when interested in nasal bacteriology, I was inclined to believe in the prophecy of Walb, which I quoted in a paper[1] before the American Medical Association, at Newport. "I am convinced," he says, "that the way opened by Löwenberg will lead to the discovery of the nature of ozæna. Whether the Löwenberg coccus, or some other, is the cause of ozæna is of no consequence; it must exist, and it is to be hoped that it will be found."

As explaining the cause of atrophic rhinitis, it is probable that this prophecy will remain unfulfilled; on the other hand, it seems to me exceedingly probable that sooner or later all will agree that the ozæna proper, *i.e.*, the characteristic odor of the secretions, is caused by the presence of micro-organisms.

There are many bacteria which, growing on ordinary culture media, give off a faint odor which is not unlike that of ozæna. I examined the secretions from three cases of marked ozæna accompanying atrophic rhinitis, by cultures on gelatine, agar-agar, and blood-serum plates, as well as in tubes of various culture media. All the routine precautions of bacterial technique against external contaminations were observed. In one case the only organism found on repeated examinations was the proteus vulgaris, its exuberant growth crowding out all others. In two cases were found, among other varieties, in sparse numbers, a short bacillus which corresponded closely with the one described by Hajek,[2] and called by him the "bacillus ozænæ fœtidus," except that it produced no local or general reaction when injected beneath the skin of rabbits. The odor of the artificial growths was identical with that of ozæna, and on blood-serum very pronounced. Klammann[3] and Thost,[4] and also Hajek, found Friedländer's capsuled pneumonia bacillus. Löwenberg's coccus was also said by the discoverer to emit an odor identical with that of ozæna.

Until, however, a micro-organism is constantly demonstrated in the superficial layers of the atrophied mucous membrane, and it is shown that inoculations produce the disease, we must be satisfied with believing that micro-organisms are responsible only for the characteristic odor of the altered secretions of atrophic rhinitis, in which they find a suitable medium for their growth. It is probable, from what has thus far been reported, that several microbes are capable of producing the odor when growing in the secretions.

The conclusions of Massei, from the experiments of Arena, that the odor is formed at the moment the secretion is passing through the mucous membrane, is not supported by sufficient experimental or clinical evidence to make it convincing. The same may be said of the surmise of Jurasz, that the odor is already present when the secretion comes out of the glands. The clinical argument against these assertions is that even the most offensive case, after having the secretions thoroughly removed and the nose perfectly cleansed, will for some hours be almost, if not entirely, freed from the odor. Transudation and secretion go on constantly, more rapidly probably in a clean nose than in one occluded by crusts. Hence the cleansing of the nose would be of little or no avail in relieving the patient, even temporarily, of the odor, if the suppositions quoted above were true.

It is probable that the symptoms of atrophic rhinitis are self-limiting, that after a longer or shorter time, extending always over years, these patients are relieved of their sufferings and terrible affliction. Otherwise we should see more cases after forty years of age than we do. It is not reasonable to suppose that regeneration of

the constituent parts of the mucous membrane takes place at an age when the tendency with other organs and tissues is toward atrophy and retrogression of function; but the question has often arisen in my mind, What becomes of these cases? If they don't get well they must die, for it is not a disease the symptoms of which can be disregarded. The number cured by any medicinal means must be very insignificant. The patient, after anosmia has become complete, may become reconciled to his own condition—not so with his friends, and he would inevitably be driven to the doctor's office; yet it is the great exception to see a case after thirty-five years of age. Possibly these cases may be cured by the suppression of secretion altogether from the complete atrophy of the mucous membrane, and, there being no more secretions to decompose, the odor and crusts both disappear. Clinical experience, however, induces me to regard this suggestion as very improbable.

Contrary to the generally received belief, this disease is fully as amenable to treatment as any chronic affection of any kind not curable by surgical means. It is almost universally good in patients under the age of thirty. From thirty to forty they may expect a fair amount of permanent relief. After forty-five treatment probably has no effect in hastening nature's cure, but great temporary relief may be given by the thorough cleansing of the nasal fossæ at regular intervals.

After such positive assertions as the above, it is necessary to qualify them by saying that I am convinced of their truth, provided the patient and his adviser do not expect miracles, and are willing to work faithfully, persistently, and intelligently for the desired result. It is impossible to understand how anyone with any knowledge of nature's laws obtainable in even the crudest medical education, should expect to arrest and turn back to a normal condition in a few weeks a process which has advanced slowly for years. One should never be led away by the glowing accounts of brilliant cures from a few applications of some lauded agent. One can always be sure that the explanation is a faulty observer, a mistaken diagnosis, or a vivid imagination. Neither clinical experience nor pathological knowledge should lead us to expect any such results, and they do not ensue upon any plan of treatment that does not extend over a long period of time. Observers whose names carry weight in the laryngological world make no such claims. When a cure is effected after many months, it is even then not a question of the restoration of the diseased tissue to its normal anatomical structure; it is simply a stimulation of the remaining glands, epithelium, and blood-vessels to do the work of their dead-and-gone congeners. It is a symptomatic cure, and not an anatomical one. Someone has said that a mucous membrane once inflamed, however slightly, never returns to its normal condition. The hyperbole of this statement makes it a little ridiculous without the definition of what constitutes a normal mucous membrane, but when atrophy has once occurred the declaration is literally true. This, however, is a part of the subject which does not particularly interest the patient. For him the disease is made up of his terrible symptoms, and the abolition of these will entirely satisfy him. As to the length of time it will take to do this, that is always a matter of many months, but will depend largely upon the length of time the affection has existed, upon the extent of the pathological changes in the mucous membrane, and upon the general health, age, and natural recuperative power of the patient. This last factor is always an unknown, but a very important one, which can be ascertained only after treatment has commenced. The instances of quick cure of the symptoms of atrophic rhinitis referred to above, where not existing in the imaginations only of those reporting them, are those cases where advanced atrophy is not present, where the majority of the secreting glands still preserve enough vitality to resume work promptly when once their mouths are freed from the obstruction of crusts.

The first thing to be done in starting to treat a case of advanced atrophic rhinitis is to give the patient thoroughly to understand what she is to expect. She must be told that the treatment must extend over a period varying from six months to a year, possibly a year and a half. From four to eight months, it will be necessary that she should come regularly to her physician every other day; after that once a week. She must cleanse her nose in the intervals at home as thoroughly as possible, several times a day. Unless she will consent to be thus faithful and persistent, it is better that she should not begin treatment at all, as the result will be a disappointment to the patient and a loss of prestige to the physician. She should be assured that if this plan is adhered to she will in a few weeks be greatly relieved of her sufferings, and after six months will have attained some permanent benefit; while in a year's time her nose will be in such a condition that by moderate daily cleansing she can remain practically cured of her ills. Of course these figures in regard to time are not meant to be absolute, but will vary either way with each case. Unless there is perfect confidence established and a thorough understanding of the difficulties of the case impressed on the patients, it is useless to attempt to treat them. With such relations, however, I know of no affection of the nose or throat in which more satisfactory results can be obtained, and more gratitude elicited from the patients by treatment. Their troubles are real, both of body and mind. Their afflictions are visited both on themselves and their associates.

It is said that "cleanliness is next to godliness," but in the treatment of atrophic rhinitis with ozæna, cleanliness takes the lead. No treatment will be successful without the frequent and regular cleansing of the nasal fossæ. By this I mean not only the removal of the crusts, but the careful washing out of all traces of muco purulent matter. It is needless, and would be superfluous here, to go into the methods of accomplishing this. Suffice it to say, however, that the crusts should always be removed by the gentle use of a probe protected by absorbent cotton, before any fluid application is made to the nose. Oily substances especially, but also watery solutions, make the crusts more tenacious and difficult of removal. Sprays of peroxide of hydrogen transform the inside of the nose into a mass of frothy, semi-gelatinous matter which clings to the mucous membrane with the tenacity and persistence of fresh glue. Every procedure must be attended with the greatest care, so as not to cause the patient unnecessary pain, if she is expected to return to you with the necessary regularity and persistence. After the crusts are removed the semi-viscid secretion can best be washed out by the use of the post-nasal syringe and the compressed air apparatus, using some weak alkaline antiseptic wash as Dobell's solution, or Seiler's dissolved tablets, or Leffert's formula.

Those cases in which the atrophy and crusts are principally found in the deeper parts of the nasal chambers, while some hypertrophy, or a less degree of atrophy, exists anteriorly, are particularly hard to cleanse properly, and the comparative anterior obstruction increases the disposition to the retention of the secretions when they form again after the cleansing. These cases are not infrequently met with.

The nasal fossa once thoroughly cleansed, we must now select some method of stimulation to the mucous membrane. The operator's mind must be disabused of any impression that there is any such thing as a specific agent for this purpose. Stimulation here means irritation. This must gradually be increased in strength until the limit of tolerance of the patient is reached, for after a time she will be able to bear with comfort degrees of local irritation which it would have been impossible to use at first. The forms of irritation are three: mechanical, electrical, and medicinal or chemical.

Mechanical: Gottstein's tampons, massage.

Electrical: 1. Galvanism. 2. Galvano-cautery at a dull red heat.

The multitude of drugs used for this purpose is not exhausted by the following list: thymol, menthol, aristol, iodol, salol, ichthyol, eucalyptol, carbolic acid, boric acid, salicylic acid, tar water, resorcin, iodoform, red gum, sanguinaria powder, galanga powder, nitrate of silver in powder and solution, bichloride of mercury, capsicum, sulphurated waters, iodine and its compounds.

All these substances have been urged as of great efficiency in the treatment of atrophic rhinitis. In order to obtain good results, however, the cleansing must be thorough, frequent, and regular. This done, good results may be obtained with anything as a subsequent application. The powders used as such, which are insoluble in the nasal secretions, act beneficially probably only by the mechanical irritation they may cause. Those antiseptics are best which irritate and which do not coagulate the secretions. Those which have toxic power it is necessary, of course, to use with great caution. My personal experience extends to a thorough trial of galvanic electricity, Gottstein's tampons, thymol, menthol, aristol.

Of the others I know nothing except from the statement of those who, enthusiastically or otherwise, describe them. Galvanism, proposed by Shurley [1] and used by Delavan [2] and Hartmann,[3] I used for three months on all cases of atrophic rhinitis. It did fairly well, but was difficult to apply, required a battery, which is always the operator's bête noire—a thing full of caprices and vexatious surprises—and often caused, even with the most careful manipulation, some pain.

Gottstein's tampons of antiseptic absorbent cotton also stimulate the watery secretion of the nose, but are apt to cause headaches, prevent the patient from blowing the nose, are apt to drop into the throat, and if left in for more than a few hours are dirty and disagreeable. Nevertheless, in some cases they are efficacious. Menthol has a tendency to cause contraction of the blood-vessels at first, and thus prevents transudation. Aristol in powder I used in all cases for two months; I believe it to be entirely inert except for some slight mechanical irritation. It is insoluble, and the practical results from its use coincide with what we should theoretically expect. I have had no experience with it in oily solutions.

Thymol I have used for four years without interruption, except to test one of the above remedies, which in each case was abandoned. The advantages thymol possesses are: it is a good antiseptic; it has a pleasant odor; it is sufficiently soluble for sprays and douches; it stimulates the mucous membrane and causes a profuse watery secretion; it is not poisonous and has no constitutional effect; it has no vascular constringing power.

Almost as much can be said of some of the other drugs, and I do not assert that it has any great advantage over them. It is simply a matter of personal preference. I use the formulæ recommended by Seiss:

No. 1.

℞. Thymol ..... gr. jss.
Alcohol,
Glycerine ..... ää ʒ jss.
Aquæ dest. ..... ad ℥ j.

Or

No. 2.

℞. Thymol ..... gr. ss.
Alcohol,
Glycerine ..... ää ʒ ss.
Aquæ dest ..... ad ℥ j.

It is convenient to make use of the stronger formula, and to dilute it at first and gradually increase it again to full strength. A fine spray with a pressure of twenty pounds is the best method of applying it. Occasionally even the weak strength causes pain at first. A solution of thymol, gr. jss. to albolene, ʒ j., may then be used with advantage. Much stronger solutions can be used with the oils than with water, but they stimulate much less, and the best results are attained by the latter.

This process of cleansing the nasal fossæ and the stimulation of the mucous membrane, must be repeated every other day for many months, and then, as it is found that the patient is able to keep it clean in the intervals at home, those intervals may be lengthened gradually to twice or once a week, and once in two weeks.

It is necessary that the patient should use a cleansing solution at home. Seiler's tablets or the Dobell solution may be used by means of syringe, spray, or douche-cup. The latter is the best. An ordinary feeding-cup such as is used for bed-ridden invalids, with a long, slender spout, may be used to flood the nose several times daily, using large quantities of the fluid each time, and blowing the nose forcibly in order to dislodge all the secretion possible. A few puffs from one of the many vaporizers of albolene with thymol may then be used in each nostril to obtain gentle stimulation.

The danger of middle ear trouble, in these cases, from syringing or spraying is practically nil, because the fossæ are usually so roomy that there is no obstruction to the return flow, and the inflow depending entirely upon gravity, no pressure can be exerted upon the mouths of the Eustachian tubes. I have never seen a case of ear trouble in atrophic rhinitis resulting from nasal douching. Indeed, contrary to the statements of Beverly Robinson,[4] I have rarely seen aural complications from any cause in cases of atrophic rhinitis, though I have not examined for slight defects of hearing, which might easily be overlooked.

In many cases it will be noticed that there are constant places on the nasal mucous membrane where secretions are especially apt to lodge and cling. These areas may be large or small. The application of a solution of nitrate of silver, ʒ j. to ʒ j., on cotton, may be made from time to time to these places. A few applications will frequently prevent the further obstinate clinging of the secretions at this spot.

The first thorough cleansing of the nose will be more difficult and painful than any subsequent one if the patient return at frequent and regular intervals. After a month or six weeks it will usually be noticed that the dried secretions are less abundant and cling less tenaciously. The patient will also say that the discharge from the nose has greatly increased. This is because the secretion is becoming more fluid and is consequently expelled before it dries. There will be periods over several weeks when the disease seems practically unchanged for the better, but this is sure to be followed by another period of great improvement. Gradually it will be seen that the nose has fewer and fewer crusts in it, the odor becomes gradually less and less strong, and the intervals during which it is absent altogether become longer and longer. The headaches disappear, and in some cases these signs of local improvement are accompanied by a corresponding improvement in the general health.

When the patient is able to go for a week or ten days without help in cleansing her nose, and without a return of the odor or other symptoms, we may conclude that some permanent benefit has been attained. The case should not be dismissed, however, until the mucous membrane is seen to be constantly moist, pink, and free from dried secretions.

When the general health is poor, tonics, exercise in the open air, a full diet, careful attention to digestion and the condition of the bowels is always demanded. Indeed, even in those cases where the general health seems perfect, fresh air and plenty of it, with more or less vigorous exercise, must be insisted on where they are possibilities. These patients, even in moderately good health, often do better locally when taking cod-liver oil or cream.

THE ARACHNOID OF THE BRAIN.[1]

1. Its General Homology with the Serous Membranes of the Other Great Cavities. 2. The Communications of Its Cavity with the Subarachnoid Space.

By F. W. LANGDON, M.D.,

PROFESSOR OF SURGICAL ANATOMY IN MIAMI MEDICAL COLLEGE, CINCINNATI.

Modern works on human anatomy do not give, as a rule, an account of the cerebro-spinal arachnoid, which is, in the opinion of the writer, in harmony with its structure. topography, and relations as shown by dissection.

Some of the different views which have existed respecting the subject, as well as the present consensus of opinion of our commonly accepted authorities, are exhibited in the following historical notes:

According to Bichat,[2] "in the middle of the seventeenth century it began to be suspected that" . . . the arachnoid and pia . . . "might possess a separate existence." "The Anatomical Society of Amsterdam assured themselves of the fact in 1665; Van Horne soon after demonstrated the arachnoides separately to his pupils."

Bichat himself [3] describes the arachnoid as a serous shut sac, conforming in all essential particulars with the serous membranes of the other cavities. This was apparently the generally accepted view up to the time of Kölliker, who wrote:[4] "It is generally stated that the inner surface of the dura mater is covered by an outer layer of the arachnoid; but nothing is found here excepting an epithelia composed of polygonal cells, and there is not a trace of a special membrane."

The same writer (page 238), speaking of the spinal membranes, says: "The inner surface of the dura mater is covered with a multiple layer of pavement epithelium cells, but has no other investment which could be regarded as a parietal lamina of the arachnoid." Again, Frey [5] says: "The arachnoid, which has also been numbered among these (the serous membranes), has no parietal layer." And, "The second membrane, the arachnoidea, was formerly described as forming a shut serous sac, but erroneously so; the parietal leaf being usually represented as fused together with the outer layer of the dura mater, since it could not be demonstrated separately." [6]

Without multiplying references unnecessarily, it is sufficient to state further that in the various editions of Gray's "Anatomy," previous to 1870, the arachnoid is described as a shut sac. Darling and Ranney, 1882, also teach this view; while Gray (after 1870), Holden, fifth edition, 1885, Leidy, 1889; Weisse, 1886, and other leading works in common use as text books, speak of it as consisting of one layer only—the "visceral" layer.

It has occurred to the writer that this question of one or two layers was one which it was desirable to have settled, and if possible by macroscopic rather than microscopic evidence. With this object in view a series of dissections were made as follows:

First dissection: Fœtus at term, stillborn.—The scalp being removed, a section of skull was made in the parietal region, removing the bone only. The following features were then easily demonstrated in successive order: 1. Periosteal layer of dura, traceable to its continuity with the sutural "ligament." 2. The dura proper (subserous connective tissue), forming the walls of sinuses and carrying the nutrient vessels for, 3, The parietal layer of arachnoid, a thin pellicle separable with the handle of scalpel. 4. Space between parietal and visceral layers of arachnoid, or the arachnoid cavity proper. 5. Visceral layer of arachnoid passing over sulci, etc. 6. Subarachnoid space. 7. The pia mater. 8. The convolutions.

Second dissection: Fœtus at term.—This was practically a repetition of the first, except as to region, the frontal bone being removed instead of the parietal.

Third dissection: Adult, negro, aged about thirty-five, brain and membranes normal.—The dura covering vertex and forming falx cerebri and tentorium was found to be inseparably united with the parietal arachnoid; at the base of the skull, however, and especially in the region of the sella turcica and orbital plates, the two membranes are quite freely separable with an ordinary scalpel, and the arachnoid could be stripped off in places. This separation also was more marked at the points of exit of the larger cranial nerves—*e.g.*, the optic. The following diagram (*A*) will show at a glance these points in the parietal region of the new born infant—the only change in adult life being fusion of the vertical parietal arachnoid with the subserous dura, a condition in every way similar to the conditions which exist in the pericardium. At the base of the skull, however, the separation is readily appreciable in the adult, as already stated.

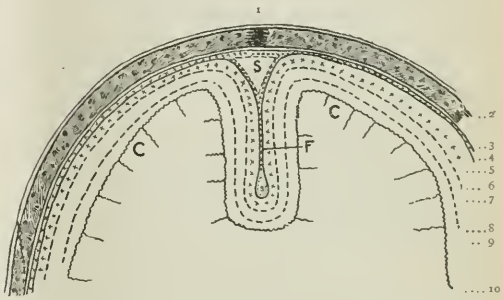

Diagram A. Vertical Transverse Section of Parietal Region to Show the Various Membranes and their Layers.—1, Sutural "ligament," continuous with external periosteum and periosteal layer of dura; 2, parietal bone; 3, periosteal layer of dura; 4, inner layer of dura, forming sinuses; 5, subserous connective tissue, between dura and parietal arachnoid; 6, parietal arachnoid; 7, arachnoid cavity; 8, visceral arachnoid; 9, subarachnoid space; 10, pia mater; S, superior longitudinal sinus; s, inferior longitudinal sinus; F, falx; C, convolutions.

Considering the nature of the sinuses—as simply dilated veins—and the fact that the inner dura is the necessary medium for vascular supply of the parietal arachnoid, it would seem in every point of view proper to consider the inner dura as homologous with the subserous connective tissues elsewhere.

The writer regrets that material and time have not permitted these observations to be carried to their logical conclusion, by actual sections of cranial nerve exits, to show the arachnoid reflections.

2. **The Communications between the Arachnoid Cavity and the Subarachnoid Space by Way of the "Lunulate Foramina."**—During the progress of the last dissection it was evident that there were two points at the base of the cranium where the arachnoid was deficient over a considerable area on either side of the medulla oblongata. These deficiencies present the form of bilateral foramina—one on each side—and are situated in the "bridge" of visceral arachnoid which stretches across from the cerebellar lobes to the under surface of the medulla. These foramina measure about half an inch in longitudinal diameter by one-fourth inch transversely, and are crossed by three or four fibrous bands, the attachment of which to the edges of the openings produces a mutiple crescentic appearance of their margins, which suggests the name adopted above. (See Diagram B.)

[1] Read before the Association of American Anatomists at the Annual Meeting, Boston, December 29, 1890.

[3] Op. cit.

[4] Manual of Human Microscopic Anatomy, p. 237–238. London, 1860.

[5] Histology and Histo-chemistry of Man, p. 227. Appleton, 1875. Op. cit., p. 599.

As the body had been subjected to but little handling before the autopsy, and the brain was removed with special care, it does not seem likely that these openings were produced accidentally; the finished appearance of their edges and close correspondence with each other in all respects would also negative this supposition.

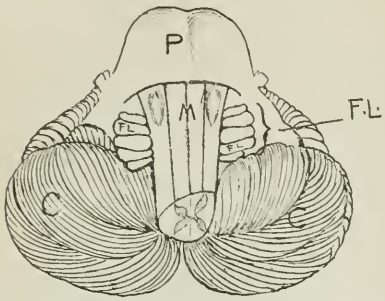

DIAGRAM B.—Lower or anterior surface of pons (P), medulla (M), and cerebellum (C), supposed to be covered by the visceral arachnoid, in which are seen the lunulate foramina (F.L.) in outline. NOTE.—The artist has failed to represent the membrane, but the outlines of the foramina are correctly placed.

It is evident that, if constant, they form a large and direct communication between the arachnoid cavity and the subarachnoid space and ventricles, just opposite the "foramen of Magendie"—by which the subarachnoid space is stated by most anatomists to communicate with the internal cavities.

Hence, it would seem reasonable to suppose that the cerebro-spinal fluid may have its origin, in large part at least, in the walls of the arachnoid cavity proper, reaching its final destination through the lunulate foramina to the subarachnoid space, thence *via* the "foramen of Magendie" to the ventricles.

Further observations on these points are therefore desirable.

For assistance and courtesies extended in connection with these dissections and observations, acknowledgments are due Dr. F. Kebler, pathologist, and Dr. George B. Twitchell, house-physician to the Cincinnati Hospital; also to Messrs. E. S. Newlin and J. G. Williams, students at Miami College.

To summarize these observations I would conclude:

1. The arachnoid membrane is a true shut sac, similar in structure and function to the serous membranes of the other great cavities. Its parietal layer is easily separable from the dura at the vertex in the fœtus and young infant, but practically inseparable in this region in the adult. At the base of the skull it is demonstrable as a separate membrane even in the adult. To assert that the parietal layer of arachnoid is absent, because its subepithelial connective tissue has fused at the vertex with the dura (connective tissue), is as incorrect as to describe the great omentum as one layer of peritoneum, because its original four layers have become matted and adherent.

2. The arachnoid cavity communicates freely with the subarachnoid space, by means of two foramina situated in the visceral arachnoid, one on either side of the medulla. For these I would propose the name "lunulate foramina," from their crescentic or lunulated edges, produced by the attachments of fibrous bands which cross the openings transversely. Subsequent observations, in two instances, confirm the presence of the "lunulate foramina." In one of these, the basilar process of the occipital and the sphenoid body were cut away from the base and the dura removed, so as to show the foramina *in situ;* thus excluding the possibility of their artificial production during the extraction of the brain.

CINCINNATI, December 16, 1890.

Typhus Fever and Cholera are prevalent to an unusual degree this year in Mecca.

THE PATHOLOGY OF THE CAISSON DISEASE.*

BY HOWARD VAN RENSSELAER, PH.B., M.D.,

LECTURER ON MATERIA MEDICA IN THE ALBANY (N. Y.) MEDICAL COLLEGE.

(Concluded from page 150.)

III. THE THEORY OF CONGESTION WITH SEQUELÆ.—The theory of congestion was the first to be enunciated, and had as its basis anatomical facts, which were proved by the autopsies. The various modifications of it will be taken in order.

a. The Theory of Congestion and "Black Blood."—The upholders of this theory are Pol and Watelle,[68] Guerard,[69] and Limousin.[70] To Pol must be given the credit of showing that the danger of accident lay, not in the increased pressure, but in its too rapid diminution. His theory is, that the effects are produced by congestions of the brain and viscera and by "black blood." They base their theory on the result of two autopsies; in neither, however, was the spinal cord opened. In both, they found congestions of the brain, lungs, and the solid abdominal organs. These congestions they stated to be the immediate sequence of the compressed air forcing the blood mechanically from the compressible peripheral tissues into the deep-lying, practically incompressible organs. This central influx of blood gives rise to visceral congestions, which during the period of compression are innocuous; because, by reason of the increased pressure, the blood absorbs and holds in solution more than its normal quantity of oxygen. Therefore, although the blood-current in the affected organs is slower than normal, yet, on account of its superoxygenation it is able to give the tissues all the nourishment they need. Now, at the moment of removal of pressure what happens? They say that Rasori, Andral, and Dubois d'Amiens have shown that it is the stupefying action of the "black blood" that becomes pernicious, and that the period of removal of pressure is precisely that in which the blood loses its oxygen. Therefore, this "black blood," *i.e.*, the blood deprived of its oxygen, and the congestions which have not had time to disappear, manifest themselves in producing the divers accidents observed among the workmen.

Bauer[3] has a similar theory, except that he does not recognize the congestions.

The amount of oxygen absorbed by the blood during the compression is really very small, as has been proved by Bert, Chabaud,[17] and others. The following table will show this:

Atmospheres.	Oxygen.	Nitrogen.	Carbonic Acid.
1	20 0	2.2	40.0
2	20.9	3.0	40.7
3	21.6	3.9	37.2
5	22.7	6.0	35.7
7	23.0	7 0	35.5
10	23.4	9.4	36.6

This table shows that oxygen increases very slowly, carbonic acid decreases very slowly, and that nitrogen is the only gas that increases very much in the blood during the increased pressure. When we consider that man is rarely subjected to a pressure of more than four atmospheres, we see by the table that the change in amount of the gases dissolved in the blood at this pressure is really trifling, and not able to account for the lesions observed. Besides, the poisoning from the effete matters in the blood would be too slow in its action to cause the very prompt effects that are so often seen, and would be more apt to affect the cerebrum first, causing headache and drowsiness, than to attack the cord.

b. The Theory of Congestion followed by Evolution of Gas.—Boucquoi[71] advanced this theory. He says that the visceral congestions, under pressure, have different reactions for solids and fluids. The former are less and less compressed according to their depth; but that the

* Being the Merritt E. Cash Prize Essay of the New York State Medical Society, 1891.

blood is under equal pressure everywhere. Hence the deep organs enclose a blood that is submitted to the same pressure as the peripheral blood, while these organs react less than those of the periphery; therefore they suffer more than these external tissues, and this difference causes the visceral congestions and hemorrhages. The pain he says results from the distention of the tissues by gas when the pressure is removed. The hemorrhages and emphysema, often claimed to be observed, are explained by a return to their normal state of gases dissolved in the blood. On their rapid conversion from a state of solution to the free state, they increased in volume sufficiently rapidly to burst the small capillaries and produce the hemorrhages. The gas in the vessels prevents the proper circulation of the blood; this in turn produces increased work for the heart, and the result is palpitation and dyspnœa, similar to that produced by injection of air in the veins. When death occurs it is due to emboli of gas in the lungs. This is a much more plausible theory than that of the formation of gas alone, as the blood current in the congested organs, coursing slowly as it does, would require much greater effort in passing the gas emboli than where no such congestion existed. As we have discussed each of these theories separately, a consideration of them combined is not necessary.

c. The Theory of Congestion followed by Hemorrhage.—Babington and Cuthbert,[1] in 1863, and Pol,[40] in 1872, and Febvre,[36] in 1879, thought that the reason that there was a predilection for pathological effects in the brain and cord, enclosed as they are in osseous cavities and having their vessels protected from atmospheric pressure, was, that they are not able to accommodate themselves as easily or rapidly to increased pressure as organs more elastic. The blood-vessels enclosed in the bony walls, not being able to expand, and unable to carry off the increased flow of blood under increased pressure, force the blood to dam back more and more, and to press on the delicate nervous structures. Thus, by the mechanical pressure, or by the rupture of the thin-walled vessels, the various symptoms are produced.

This theory is not borne out by actual facts. Hemorrhage as the result of rupture from extreme congestion is frequently met with in the kidneys, and occasionally on the dura mater of the cord. But where this lesion has occurred it has never been large enough, simply by its pressure on the cord, to cause paralysis.

d. The Theory of Congestion followed by Acute Revulsive Anæmia.—This theory has been advocated by Moxon, Gowers, and Twynam.

Moxon,[75] in 1881, took an entirely different view from anyone up to that time. His theory is, that it is due to an acute revulsive anæmia. He has proved that "the human brain is capable of withstanding enormous pressure without danger, provided that asphyxia or strangulation be not present. The real danger to the nervous system depends on the pressure being too rapidly removed." Further, he shows how paraplegia is dependent on the poor blood-supply of the spinal cord, especially the cauda equina, in consequence of the great length and small calibre of the spinal arteries.

"The blood supply is carried on by three slender vessels coming from the vertebral arteries, and these are reinforced by small branches which pass to the cord along the nerve-roots. These branches are for the most part short, nearly transverse in direction in the cervical and dorsal regions, oblique in the lumbar and sacral. Furthermore, it is to be noted that the spinal cord does not pass beyond the lower body of the first lumbar vertebra, while the spinal canal enclosing the leash of nerves which form the cauda equina extends to the end of the sacrum. Along the obliquely directed sacral nerves pass upward those delicate branches of the lower lumbar and sacral arteries which reinforce the terminal portion of the spinal arteries proper. The lumbar enlargement of the cord receives therefore its supply of blood under conditions of blood-pressure which a slight weakening of the *vis a tergo* must reduce to a minimum. This is shown by the fact that the anterior spinal artery is rarely found injected to its termination—usually, I believe, to only within a couple of inches of the filum terminale—while the vessel is found empty on the filum itself. When the pressure is rapidly removed there is a great rush of blood into the tissues of the surface of the body. The spinal cord then being very poorly supplied with blood, is in a state of marked anæmia; and I may remind you that anæmia in other cases is an early stage of white softening as met with in ordinary paraplegia."

Gowers,[46] in 1886, agrees with Moxon in that the lesion is due to a revulsive anæmia. He says, "The pressure drives the blood from the surface, and probably lessens the amount in all vessels to which its influence extends. On the removal of the increased pressure the conditions may be reversed, perhaps in a degree proportioned to the duration of the pressure. Hence the paralysis is due perhaps to an acute revulsive anæmia of the cord, analogous to that which sometimes follows loss of blood. The dorsal cord, to judge by inflammation, is more prone to suffer acute disturbance of nutrition than any other part of the central nervous system."

Twynam,[112] in 1888, thought that anæmia of the cord was the primary cause, but accounts for it in a different way. He thinks that during the period of increased pressure the brain becomes congested and presses out the cerebro-spinal fluid from the cavity of the cranium into that of the spinal canal. As the cavity of the arachnoid is larger below than above, possibly the anæmia of the lower cord may be produced by pressure of this fluid, when we consider the hydrostatic relation of the long column of fluid pressing the blood out of the tissues of the cord, with the increased pressure in the brain, representing the power, and the lower end of the cord the part to be compressed; lying as it does in that part of the cylinder where the diameter is large, and therefore the pressure is greater, an anæmic condition is produced, and the longer this is continued the worse for the workmen.

This theory is an ingenious one and might account for all the microscopic lesions of the cord. But if the real lesion was due to a revulsive anæmia, we should find the cord anæmic at the autopsy. As a matter of fact we have found, as is shown in the summary of the autopsies (page 146), that the cords of persons dying suddenly from the caisson disease are almost invariably congested.

e. The Theory of Congestion followed by Comparative Stasis.—Of all the theories hitherto advanced, this one seems to be the most scientific and the most trustworthy, based as it is on the results of the autopsies, and supported by anatomical facts.

Smith[103, 104] and Nixon[81] advocated this theory. After speaking of the congestion of the deep organs during the increased pressure, Smith says, "If, now, the external pressure is suddenly removed, what will be the result? Vessels which have been compressed and almost emptied of blood will now offer new channels through which the blood can rush; and vessels overcrowded with blood, with their walls paralyzed by over distention, will have the current within them slowed almost, or quite, to the point of stopping. The vessels of the brain and spinal cord, being within bony walls, where the direct pressure of the condensed air could not affect them, will be found the most distended and the most helpless to relieve themselves. They will get little aid from the *vis a tergo* of the circulation, for the blood will find easier courses by other ways, vascular tension being almost nil, and the vaso-motor system out of repair."

Nixon, in 1889, also considers the lesion to be due to deficient blood-supply; he says, "The blood-pressure in the cerebral and spinal vessels is suddenly lowered at a time when the vaso-motor system is out of order, so that although the vessels are full of blood, the circulation becomes slowed and areas of stasis may be formed which,

affecting the nerve-elements, give rise to symptoms of nervous disturbances, such as pain, paralysis, and vertigo." He then quotes Professor Birmingham, who mentions a very curious point in reference to the length of the reinforcing sacral arteries — that corresponding to the third or fourth sacral nerve was eight inches in length, of very small calibre, and injected at its lower part from the lateral sacral artery for a very short distance; while the part in immediate connection with the anterior spinal artery was also injected, but the intervening part of the vessel was found empty.

"Thus it is seen that the end of the spinal cord, corresponding to the innervation of the lower limbs and sphincters, receives a supply of blood under conditions which circumstances may render precarious, for any sudden diminution of blood-pressure may lead to such a reduction of blood-supply as to produce profound functional disturbance. This may be aggravated by any sudden increase in the passage of the cerebro-spinal fluid within the theca spinalis. What probably helps to avert disturbance of nutrition depending upon defective blood-supply in this situation, is the larger number of reinforcing arteries at the lower segment of the cord than elsewhere. I believe that the peculiarities of the circulation just described account for the paraplegia developed in divers being usually of a transient nature; and I believe in cases of chronic nature, the sudden disturbance in the circulation leads to such nutritive changes in the cord that a myelitis was set up in that part of it which is, *par excellence*, the seat of inflammatory change—viz., the dorsal segment."

As its fundamental basis, this theory recognizes the congestions found at autopsies. The idea that the circulation becomes very slow and is insufficient to nourish the lower part of the cord is strengthened by the anatomical arrangement of the blood-vessels in that part of the cord, as has been pointed out by Moxon and Birmingham. That sudden cessation of circulation will set up an almost instantaneous paralysis, and an extremely acute inflammation of the cord, has long been known. Herter's[55] experiments in this direction are very interesting. He employed the method of Stenson modified by DuBois-Raymond. "This consists in passing a curved needle through the abdominal wall on one side of the vertebral column and bringing it out on the other, in such a manner as to include, among other structures, the abdominal aorta and vena cava. The needle carried a strong ligature, which is tied so tightly over the back of the animal as to effectually compress the abdominal vessels. The effect of this proceeding is to produce an almost instantaneous paraplegia. If the compression be exercised for a shorter time than three-quarters of an hour, the paralysis wears off rapidly. If, however, effectual compression be continued during a period greater than one hour, the paraplegia becomes a permanent condition. In the great majority of instances the onset of the paralysis is so closely connected in time with the tightening of the ligature that it may be considered coincident with it. In some cases, however, several seconds pass before the paralysis is evident, and occasionally the time is several minutes."

In the case of workmen coming out of the caisson the blood-current is slowed or stopped for two reasons: First, by the long continuance in the caisson, from one to four hours, the vessels in the deep-seated organs by continued over-distention become paralyzed, and are unable by loss of their tonic elasticity to help propel the blood that is already in them. Second, pressure being removed, the current of blood rushes into peripheral organs and occupies vessels partially emptied by the previous pressure, where the resistance is slight. The *vis a tergo* then being removed or greatly diminished, and the vessels themselves being incapable of emptying themselves promptly, the current is so slowed or absent that small thrombi may be formed in various minute vessels. Whether thrombi are formed or not, the nutrition of the cord suffers sufficiently to produce a rapid or slow, complete or temporary paralysis, or pain only, depending on the extent of the congestion and subsequent stagnation of the blood-current.

There are a few other clinical facts supporting the theory of congestion, as opposed to the gaseous theory, to which attention should be called.

1. *Increase of Urine.*—As early as 1820 Hamel mentioned the marked increase in the amount of urine voided by the workmen under compressed air; since then most writers have referred to it, it having been especially studied by Jaminet.

There is nothing in the gaseous theory to account for this clinical fact. Reasoning from the congestion theory, it would be expected, because, first, there is an increased amount of blood under increased pressure flowing through the kidneys during the compression; secondly, the skin being to a great extent deprived of its blood-supply, ceases to act, and thus compels the kidneys to do the work for which the skin is at present incapacitated.

2. *Alcoholism and Debility.*—Persons with marked alcoholic habit, or whose system is below par, from any cause, are found to be the ones most liable to be attacked. In the gaseous theory, which is a mechanical one, the gas would as effectually block the vessels of a strong man as of one whose vessels and vaso-motor system were deranged by excess or sickness. While on the congestion theory, any inherent cause tending to reduce the tonic elasticity of the vessels would predispose to the gravity of the congestion.

3. *Obesity.*—Fat men are known to be more severely attacked than those of a spare habit. Again, in the gaseous theory this would make no difference, as the same amount of blood circulates in the vessels of the cord, be the person fat or lean. On the congestion theory this is an important factor. Though normally the amount of blood in the cord of the stout and thin is the same, yet the total quantity of blood in the obese is much more than in the spare, and when atmospheric pressure is applied, more blood is driven from the periphery into the deep organs, and so the danger of accidents is greater in the case of the fat man.

4. *Repeated Exposure Protects.*—Long continuance of work, with gradually increasing pressures, protects.

Clinical experience teaches that persons working for the first time are the ones most exposed to attack. This is again opposed to a strictly mechanical theory; while it is evident that under slow progressive pressure the vessels of the deep organs can gradually become strengthened and accustomed to the changes of pressure, as is seen also among birds and amphibious animals.

5. *Duration under Pressure.*—The greater the length of time under pressure the greater the danger. According to Dalton's law, as soon as the blood becomes saturated it cannot absorb any more gas under that pressure, so that after the first few minutes' sojourn at the maximum pressure, the blood becomes saturated and is incapable of further absorption. Therefore, under the gaseous theory, the length of time that a person remains in the caisson after saturation of blood is immaterial. With the theory of congestion the contrary is true. The longer the vessels are distended with blood the more their walls become weakened, and the less able they are to resist the pressure, and the less able to empty themselves; hence the greater danger of paralysis of their walls, or rupture producing hemorrhage.

6. *Cold and Moisture.*—Jaminet and others have shown that during the removal of pressure the temperature of the air-lock falls with great rapidity—as much as seventeen degrees in four minutes—so that, by the time that the pressure is removed, the moist atmosphere in the air-lock is nearly at the point of freezing. This sudden change of temperature must have a very deleterious effect on the workmen, who are tired, hungry, and covered with cold sweat; and must markedly weaken the vaso-motor system and tend to repress reaction.

Conclusions.—From the mass of evidence compared and studied, it seems evident that the pathology of the caisson disease is due to congestion and consequent malnutrition of all the internal organs, and especially of the spinal cord. This congestion is due in part to paralysis of the vessel walls from previous over distention, and in part to the lack of *vis a tergo* of the blood-current, because the blood finds easier passage through the peripheral vessels, which have been partially emptied by the previous pressure. This comparative stasis of the blood causes a malnutrition of the tissues, which is manifested especially in the organ invariably found congested, the spinal cord.

The exciting causes are: Long-continued pressure, great amount of pressure, rapid removal of pressure, exhaustion and cold during the removal of pressure, and, possibly, evolution of gas if the withdrawal of the pressure is very sudden, *i.e.*, one-half to one minute.

The predisposing causes are: Obesity, old age, alcoholic excesses, heart and kidney disease, lowered vitality of the body from any cause.

The pathological lesion of the cord, in most cases of paraplegia, is a disseminated myelitis, involving the nerve-fibres, neuroglia, and blood-vessels of the white matter, especially of the posterior and adjacent parts of the lateral columns, and producing ascending degeneration of the columns of Goll and the direct cerebellar tract, and descending degeneration of the crossed pyramidal tract, and leaving the gray matter unharmed.

It has its seat in the dorsal region of the cord, because this portion is physiologically and anatomically the least resistant part of the nervous system, and attacks principally the postero-lateral columns, on account of some anatomical arrangement of the smaller blood-vessels not thoroughly understood.

Progress of Medical Science.

The Action of Cocaine on the Circulation.—Dr. Edward T. Reichert, from a careful study of the actions of cocaine on the circulation in animals, deduced the following conclusions: 1. The discrepancies in the testimony offered by different experimenters, in their investigations of the action of cocaine on the circulation, are almost wholly due to variations in the absolute doses employed, and to the individual susceptibility of the animals. 2. The minimal fatal dose, when injected intravenously in divided doses in the form of a one per cent. solution, varies from 0.004 to 0.03 gramme to the kilo of the body weight. Owing to the great differences in the sensitiveness of different dogs to the poison, a moderate dose in one animal might prove a small or a large one in another of similar weight. 3. When the full train of effects on the heart-beat is slowly developed by the repeated injection of very small doses (0.001 gramme to the kilo of body weight), the pulse rate is at first decreased, then increased, and finally decreased. A single very small dose causes a decrease, a small to a moderate dose an increase; large doses a transient decrease followed by an increase; very large doses a more or less permanent decrease. The primary decrease, which only can be developed by very small doses, is due to a stimulation of the cardio-inhibitory centres; the secondary increase to a depression of the same centres, and which may be assisted by a similar action on the cardio-inhibitory peripheries; and the final decrease to a depression either of the accelerator or automatic motor-ganglion in the heart. The height of the pulse curves during these changes is always in inverse relation to the frequency of the beat. 4. The cardio-inhibitory centres are invariably affected, being primarily stimulated, and secondarily depressed; but the action on the peripheries is of a very inconstant character, although a primary stimulant action is never manifest the depressant action is sometimes present to a profound degree very early in the poisoning, and, at others, absolutely absent up to the time of death. 5. The arterial pressure is always increased, unless it be after large doses, when it may temporarily be diminished, followed by a rise above the normal; or after very large doses, be permanently lowered. The increase may be decided long after the development of the third stage of the actions on the heart, and, therefore, may outlast the period of the acceleration of the heart's beat. The increase is chiefly due to a stimulation of the vaso-motor centres in the medulla oblongata; to a slight stimulation direct of the vessel walls; and to the acceleration of the pulse. The final fall of pressure is chiefly dependent upon a depression of the heart, and partly to vaso-motor depression. 6. The effects of cocaine in normal and curarized animals are identical, unless, in the latter, the curare has been used to excess. 7. Cocaine is a decided circulatory stimulant.—*American Lancet.*

Treatment of the Night-sweats of Phthisis.—Huchard reports the results with many medicaments tried for the relief of the sweating of phthisical patients. Among these may be mentioned lead acetate, tannin, phosphate

of lime, ergot, atropine, and muscarine. Of these the two first are unreliable, and are seldom used. Probably atropine sulphate is the most valuable (one-half to one milligramme at night). Phosphate of lime should be given in large doses (one or two drachms daily) to produce anhidrotic effects, and even in these doses it has sometimes failed. Ergot (fifteen to twenty-two grains of the powder at night) is much more reliable. When the sweats co-exist with more or less marked fever, the author recommends the use of quinine combined with ergot.

℞ Quinæ sulph..... .... gr. xvi.
Pulv. ergotæ .... ℥ ss.
Divide into four cachets—two or three to be taken daily.

This formula is especially valuable in phthisis with hæmoptysis. Lastly, powdered agaric is an excellent remedy, not equal to atropine, but perfectly harmless, and never causing derangement of digestion. It may well be combined with tannin or belladonna, given in doses of three or four grains. The same writer speaks very highly of antipyrin in the initial fever of tuberculous patients. The older drugs, quinine, tartar emetic, salicylic acid, all fail, or have but slight effect. It is especially in this initial fever that antipyrin is of great service. One must, however, distinguish between an analgesic and an antipyretic dose of the drug. To obtain the former effect, one would give a large dose (say fifteen to thirty grains) in a short time, but this must not be done if its best action as an antipyretic is desired. It is well for this purpose to use constantly decreasing doses (say sixteen grains, twelve grains, eight grains) taking care to divide them so that at no time during the twenty four hours is the patient not under the influence of the drug. Used in this way, Huchard declares that antipyrin seems to have a special action on the tuberculous lesion, and to greatly retard or to arrest its progress. Professor Combemale has used tellurate of sodium in phthisical and other sweating. It was first recommended by Neusser, who gave one-third or two-thirds of a grain in pill once daily. Combemale gave it up to nearly one grain per dose, and tried its effects in eleven cases. His conclusions are, it is a powerful anti-sudorific; a dose of nearly one grain gives the best results; it gives rise to digestive troubles, and especially to a strong garlic odor in the breath. All the compounds of the tellurium cause a very disagreeable odor in the breath, and this must always be a bar to their employment, as it is very persistent and disagreeable.—*Canada Lancet.*

What is the Best Nutritive Enema?—Nutritive enemata, though often indicated in cases of œsophageal or gastric disease, are comparatively rarely used, because of the general scepticism as to their utility. Either they are of but little nutritive value, as in the case of bouillon, or they are difficult of absorption by the rectum, as in the case of milk. Leube suggested, in 1872, the use of pancreatized beef pulp, and afterward Ewald proposed the peptones of meat and of cheese as offering suitable material for rectal feeding. There is no doubt that the substances recommended by these writers are, in part at least, absorbed by the rectum. Nevertheless, their use has never become general, because of the difficulty of their preparation. Ewald, as a result of further experiments, found that eggs, even though not peptonized, were to a considerable extent absorbed by the rectal mucous membrane. According to the *Mercredi médical*, Huber, of Zurich, has recently repeated Ewald's experiments in Professor Eichhorst's clinic, and announces that the absorption of the raw eggs is greatly aided by the addition of common salt. The salt is well borne, and causes, as a rule, no irritation of the bowel. He considers that eggs beaten up with salt, in the proportion of fifteen grains to each egg, are the best form of nutritive enema. His method of procedure is as follows: Two or three eggs are taken and thirty to forty-five grains of salt are added to them. They are slowly injected by means of a soft-rubber tube carried as high up into the bowel as possible. Three such enemata are given daily. An hour before each enema the rectum is cleared out by means of a large injection of warm water.—*New York Medical Journal.*

Hydrochlorate of Phenocoll.—This new antipyretic, has the marked advantage of being relatively very soluble in water. Since the first announcement the compound has been tried in a number of cases of phthisis and rheumatism by Dr. Hertel, with results sufficiently important to be worthy of special mention. The first two cases in which the author gave phenocoll were patients suffering from phthisis ulcerosa cavernosa. In the first case quinine and antipyrin had been previously given, and uselessly, before the new remedy was tried. Thirty, sixty, and seventy-five grains were administered daily in fifteen-grain doses. During the whole time of the application of phenocoll no disturbing effects of any kind were observed in the functions of the heart, lungs, or digestive organs. The febrile temperature was generally reduced 1° C. by fifteen grains within a few hours; in one case the reduction amounted in one hour to nearly 2° C. The effect was generally very transient, but when the febrile temperature recurred it was without shivering or perspiration. The only physiological sign of the excretion of the remedy was a dark brownish-red color in the urine, which deepened on exposure to air, or on the addition of ferric chloride. In the other cases of phthisis, phenocoll was given in eight-grain doses with little or no effect upon the temperature. No unpleasant subsidiary symptoms and functional disturbances were ever observed. More striking results were obtained in the treatment of acute rheumatism of the joints, characterized by painful swellings, hindering or quite preventing movement, and more or less fever. Under the administration of the remedies usually employed there was no improvement, and the cases even got worse. Here also seventy-five grains were given daily in fifteen-grain doses, and, in one instance, morphine in the evening. On the day following the beginning of the phenocoll treatment improvement was commonly noted, and after about four days the joints were quite painless. The author states that in none of these cases of articular rheumatism did the remedy seem to have any effect upon the temperature. The latter was now and then reduced 0.6° to nearly 1.5° C., but only for a short time, and without any certainty. The fever generally left the patients simultaneously with the appearance of general improvement. These beneficial results were obtained after the ordinary remedies, such as antipyrin, sodium salicylate, and antifebrin, had failed.—*Deutsche Medicinische Wochenschrift.*

The Treatment of Amenorrhœa and Dysmenorrhœa by Apiol.—According to Dr. Delmis, apiol is the active principle of the seeds of parsley. It is an oily fluid of an amber color, heavier than water, having a special odor resembling that of the seed from which it is obtained; has a piquant acrid flavor; insoluble in water, soluble in alcohol and ether, and in chloroform. It was at first supposed to be a succedaneum for quinine, but observation has not confirmed this. The experiments of Joret and Homelle have pronounced it to be a valuable emmenagogue. These observations have been confirmed by many other authorities, which are enumerated. In a physiological point of view apiol is absolutely innocuous. In doses of from fifty centigrammes to one gramme it produces slight cerebral excitement, such as is caused by coffee. In doses of from two to four grammes it produces drunkenness. With reference to its therapeutic action it has an effect on the uterus analogous to that of digitalis on the heart. To produce its full effect it should be given shortly before each period.—*Le Progrès Medical.*

The Influenza is again epidemic in Moscow in very severe form, numbers being prostrated by it daily.

MEDICAL RECORD:

New York, August 15, 1891.

CULEX PIPIENS.

We all know the creature, but may not perhaps recognize him as readily under this name as under the more familiar, but not thereby despised, one of mosquito. We said "him," but we were wrong, for, unlike what is found in some of the higher orders of creation, it is the females that make all the trouble and do all the biting and stinging, the male being a very inoffensive and harmless insect, shunning man and getting his sustenance from the juices of plants, a few drops of which suffice for the needs of his short career. We might know that nothing good could ever come from the culicidæ, for they start out in life in a way that no self-respecting larva could abide, swimming around, as if ashamed of themselves or of their progenitors, with their heads hanging down in the water and breathing through their tails.

A single mosquito, buzzing about on a warm summer night, can do more to keep away slumber than the uneasiest conscience that ever pricked the soul of man for his sins; yet in this part of the world, even in New Jersey, we do not think of the creature as one that can destroy life; its limit of evil doing is as a pruritifactive and profanity-causing pest. When present in large numbers, however, they may become as dangerous to man as the rattlesnake, or as the man-eater in the Indian jungle. In an article on poisonous insects, in the "Reference Handbook of the Medical Sciences," Mr. Riley, the government entomologist, says that the pestiferous little insects "have caused the rout of armies and the desertion of cities, and the hum of an insignificant gnat may inspire more terror than the roar of the lion. The bravest man on the fleetest horse dare not cross some of the more rank and dank prairies of Northern Minnesota in June. It is well known that Father De Smet once nearly died from mosquito-bites, his flesh being so swollen around the arms and legs that it literally burst. Those who have travelled in summer on the lower Mississippi or in the Northwest, have experienced the torment which these frail flies can inflict; at times they drive everyone from the boat, and trains can sometimes only run with comfort on the Northern Pacific by keeping a smudge in the baggage-car and the doors of all the coaches open to the fumes." There are said to be more mosquitoes to the cubic inch on the Magdalena River in South America than anywhere else in the known world, and it is madness to attempt a voyage up the river without a mosquito-netting and some ammonia or other preparation to relieve the itching of the bites received in spite of constant care. A story is told of an Englishman who was not afraid of a mosquito or two, and scorned to take any precaution before starting up this river for Bogotá. He soon had cause to repent of his foolish obstinacy, and after offering vainly all the money he had for the loan of a mosquito-netting for the remainder of the voyage, he was driven mad by his tortures on the third day of the sail, threw himself into the river, and was drowned. This may be true and it may not, but anyone who has ever faced one of these dense swarms without the protection of a thick net will have no trouble in recognizing the probability of its being an actual occurrence.

But one must give the devil his due, and even the mosquito has his good points, or rather let us say *her* good points, for, as we hinted before, the male has all the gentle unobtrusiveness and innocuous artlessness of his sex in other walks of life. The larvæ, wriggle-tails as they are usually called, swim about in stagnant pools and perform a useful service in purifying the water and freeing it from many swarms of microbes that are possibly inimical to man. But it is only in her tender youth that culex pipiens is good, and as soon as she gets her wings and becomes capable of working mischief, her period of usefulness to the community is at an end.

In addition to the irritation which she excites by her bites, she has been accused of carrying about the germs of disease on her proboscis, and thus spreading contagion and defying quarantine. Dr. Finlay, of Havana, has been trying to turn this to good account by making the mosquito the instrument of preventive inoculations against yellow fever. He recently published the statistics of his experiments in this direction, from which it would seem that his method may really possess some efficacy. The insects that have been seen to bite patients with yellow fever are carried away carefully and made to sting newly arrived and unprotected individuals. Dr. Finlay reports the results of over fifty cases of mosquito inoculation, and of these but four individuals contracted the disease in a severe form within three years after the inoculation, one only dying therefrom. Of the remainder some presented symptoms of yellow fever between the fourth and twenty-fifth day after inoculation, while others had no symptoms at this time, but suffered later from a mild attack of the disease. Some significant comparative statistics were obtained from the observation of sixty-five monks who, from time to time, arrived in Havana, where they all lived under similar conditions. Thirty-three of these were inoculated, and thirty-two were not. Only two of the inoculated suffered from well marked attacks of yellow fever, which, however, did not prove fatal; whereas eleven of those that had not been inoculated were severely attacked, no less than five dying.

There are numerous patent preparations recommended as efficacious in relieving the irritation caused by the sting of the mosquito, some of which are possibly very serviceable, but probably not more so than oil of cloves, ammonia, bicarbonate of soda, chloroform, or thymol. When none of these remedies can be obtained, it may be well to remember that the alkali of ordinary soap is often as efficacious as anything. As soon as a bite is felt, the part

should be moistened and rubbed with a piece of soap, the lather so formed being allowed to dry on the skin, and in a very short time, unless the individual be unusually susceptible to the poison of the insect, all irritation will have disappeared.

But prevention is, of course, better than cure, and most people who, for their sins, must live in a mosquito country, keep off the greater number of their enemies by sleeping under a mosquito-bar, although there is always one culex that manages to get in despite the utmost precaution. These bars are a great comfort, nevertheless, and even an absolute necessity in certain regions, but they are very inflammable, and serious accidents have resulted from their being set on fire by the flame of a candle or gas-jet in the neighborhood of the bed. We may therefore fittingly bring these konopological remarks to a close by presenting the following recipe, published by the *National Druggist*, for rendering mosquito-netting uninflammable:

"Make a solution of one part of ammonium sulphate to five parts of water and immerse the netting in the same. One pound of netting will require from twenty to twenty four ounces of the solution to thoroughly saturate it. The material is entirely inoffensive, and the ease with which it is employed is not its least recommendation. After saturating the bar (or other material) with the liquid, it is necessary to pass a hot iron over the fabric to dry it and make it ready for use."

"DOES VIVISECTION HELP?"

No one is so blind as he who can, but will not, see. Under the above heading there is, in the "Open Letters" of the current number of the *Century Magazine*, a denunciation of vivisection and bacteriological investigation, signed, Edward Berdoe, M.R.C.S. It is against the workers in the latter field that his spite is especially directed. He would inoculate them with the filthy products of their own cultivations, and let them have a taste of the sufferings they inflict on the animals. He settles the hydrophobia question off hand, declaring that Pasteur has not discovered any remedy for the disease. Concerning tuberculin he says, "I know this Koch; he comes from Berlin and is going into oblivion."

From the foregoing quotations, which illustrate the tenor of the whole article, it is easy to see that Mr. Berdoe, M.R.C.S., belongs to the "one idea" school. It is characteristic of this class of thinkers that they hold on to their beliefs with an almost invincible pertinacity. There may be honest differences of opinion with regard to the value of the latest discoveries of Pasteur and Koch, but he who would place under the ban all bacteriological workers must find the closing decade of the nineteenth century a very uncongenial time. After long centuries of very slow progress, medical science has caught up with the spirit of the age, and during the last twenty-five years has advanced with giant strides. In fact, it is not too much to say that the isolation of the specific materies morbi of many of the contagions has been accomplished during that time. Human life has been lengthened. It is not fair to attribute this merely to a greater knowledge of sanitary laws, for these laws have in the main been formulated from the lessons which our bacteriological investigations have taught us.

But the anti-vivisectionists die hard. We believe they are engaged in a losing struggle, however, because they have on their side at present an ally which will some day change colors. We refer to the public at large. Men understand the rationale of vaccination, for it has been a matter of common knowledge for now these many years. Yet many intelligent men do not yet know that our information concerning contagious diseases, other than variola, is rapidly approaching that point where it will be of practical value. To remove an effect we must first get at the cause. This latter we are now slowly but surely doing, and as soon as we can present our knowledge in demonstrable form we shall have all reasonable thinking people on our side.

A NEW TREATMENT FOR ALOPECIA.

The form of alopecia for which M. Moty suggests a new plan of treatment is that which proves at times so obstinate, in spite of all applications, commonly known as alopecia areata. At a recent meeting of the French Society of Dermatologie et Syphilographie, he presented a number of patients who had been subjected to intradermic injections of corrosive sublimate in strength of two to five hundred, and claimed that the treatment had proven very satisfactory, in that the growth of hair over the bald spots had been more rapid than after other modes of treatment. A variety of vehicles had been experimented with, until it was found that an aqueous solution was the best. Several injections of not more than five or six drops are made around each patch.

Modern investigations tend to show that there is at least one variety of alopecia, occurring in rounded plaques, which is due to the invasion of a micro-organism, and the observations of von Scholen, Thin, Robinson, and others in this field have rendered it scarcely justifiable for an author at the present day to attribute the affection to neurotic causes in all cases. If, as Robinson maintains, the organisms are situated deeply in the tissues of the scalp or other hairy portions of the skin, then the plan of treatment here suggested is eminently rational, and ought to be as successful as it is claimed.

It must always be remembered, however, that the disease is of a most erratic nature, and while at times it resists all our efforts, at others it shows a tendency to rapid and spontaneous recovery.

Besnier relates an instance in point, where a patient was treated in his service continually for two years without success. He was then sent to a colleague who continued exactly the same treatment, and a cure was promptly effected.

THE FUTURE OF AMERICAN MEDICAL GRADUATES.

A few years ago, Sir James Paget reported the results of an inquiry into the history of the graduates of one of the great London medical schools. His investigation showed that a considerable number, amounting, if we remember correctly, to about twenty-five per cent., left the profession for some more lucrative calling.

Dr. W. R. Hubbert reports in the *Medical Age* the results of his investigations of the history of one hundred of his medical friends after graduation. He found that nearly seventy-five per cent. had to resort to other employments in order to make a living: 23 received a salary either in addition to practice or separate therefrom; 15 were proprietors of drug stores; 3 were insurance agents; 4 loaned money; 1 sold real estate; 3 were connected with medical journals; 1 was an agent for drugs; 1 for books; 1 preached; 1 was in the patent medicine business; 2 were farmers; 1 a manufacturer; 2 gave massage treatment; 1 sawed wood, and subsequently suicided; 12 gave up in disgust, and 1 never tried practice at all; 29 graduates only in 100 exclusively devoted themselves to medicine, and of these 11 associated themselves with other practitioners, and in many cases subsequently fell heir to their practice. In the western part of the country, that is, west of the Mississippi River, sixty per cent. of all physicians are connected with drug stores, either as clerks or proprietors. In the East the proportion is much less, being from twelve to fifteen per cent. In the West, also, forty per cent. of them have an interest in farms."

If Dr. Hubbert's friends represent the average medical graduate, a very pitiful showing is made for medical practice as a means of gaining a livelihood. Yet there are many things which make the statements given above seem probable. It is well known that in this country we have about twice as many doctors relatively to the population as in Europe. It seems to be an economic law that it takes a population of at least one thousand to support one physician, and as in America the ratio is nearly one to six hundred, it follows that nearly one-half of the medical profession must find some other means to eke out an income.

News of the Week.

Cuban Medical Congress. — The second Congress of Cuban Physicians will be held in Havana in January next, under the presidency of Dr. Juan Santos Fernandez.

Assault upon a Physician.—A physician in Covington, Ky., sent a bill to one of his patients, which so angered the man that he assaulted the doctor and injured him severely.

No Medical Law in Connecticut.—A petition is to be presented to the next Legislature of Connecticut, praying for the passage of a stringent law regulating the practice of medicine. For the absence of any effective medical law, Connecticut, Massachusetts, and a few other States are now conspicuous.

Dr. Robert Gifford died on August 10th, in Fredonia, N. H., aged sixty-three. He was a naval surgeon during the war, and was on board of the monitor Osage when it was blown up by a torpedo in Mobile Bay.

Dr. Henry Grant Keefer died recently at Honesdale, Pa., aged fifty-eight. He was born in Canada, and was graduated in medicine from McGill College. At the breaking out of the War of the Rebellion he entered the Union army as assistant surgeon, and served till the close of the war. He had practised at Honesdale since 1869. He leaves a wife and five children.

The Schoolmaster is Abroad. — The visitor to the Academy of Medicine in these dog-days is met at the entrance by a sign which informs him that "the Elevator stop for Repears."

The Law of Compensation.—Dr. Hershey reports in the *Medical News*, three cases of gastric ulcer cured without medicine by a strict diet of ice-cream. It isn't so bad, after all, to have an ulcer of the stomach.

Still Another.—The number of sure cures for tuberculosis is now so great, not to speak of those which the future will bring forth, that the disease ought to be very lightly regarded. The latest reported up to the hour of going to press is, we believe, the "guaiacol treatment" of Dr. Max Schüler. Seventy out of every hundred are said to be cured by means of iodoform injections combined with the internal administration of guaiacol.

Dr. T. H. Stuart, of Bradford, Pa., died on August 10th from the effects of a pistol-shot wound inflicted by himself. Dr. Stuart was a somewhat eccentric man in many ways, one of his theories, which he seems to have desired to put to the actual test, being that the easiest mode of death was by shooting. He was seventy-six years of age.

A Very Respectable Old Age.—It is reported that there are living in Dos-Kazan, Russia, a Kirghis peasant and his wife, each of them over one hundred and fifty years old. Their eldest son has himself reached the age of one hundred and twenty years.

Drummers for Doctors.—We rubbed our eyes, recleansed our spectacle-lenses, looked again at the journal cover, made sure it was not a summer theatre we were in —but had at last to confess that the words stood as given below. The periodical is "our esteemed contemporary," *The Journal of the State Medical Society of Arkansas*, and in its "Miscellany" there appears without comment or explanation the following: "List of Drummers for Doctors in the City of Hot Springs, Ark., to whom License has been Issued in Conformity to an Ordinance passed June 17, 1889." Since we do not wish to give a free advertisement to these gentlemen, we can only explain that the list comprises the names of twelve doctors, each followed by the names of his "drummers." One doctor has but one drummer, five have two, one has three, two have five, one has six, one ten, and one has eleven—fifty-one men "touting" and "heeling" for the doctors of one small town! The City Clerk swears the list is a true abstract of the office records, and a note appended explains that the "hotel and doctor drummers" are by ordinance required to take out a license, and wear badges showing their vocation.—*Medical News.*

The Judge's Experience Did Not Count.—Judge Cowing, of New York, stated in his charge to the jury, in a murder trial where expert testimony was employed, that he had tried a great many cases where physicians had appeared as witnesses, and it was a most remarkable circumstance that you could always get an equal number to swear on both sides of any question. The Court of Appeals set the verdict aside and scored the judge for appearing as a witness, as he "had no right to import his so-called experience as to experts" into the case.—*Medical Standard.*

Congress on Hypnotism.—The annual meeting of the French Society of Hypnology was held in Paris on July 20th and following days. The society includes, in addition to physicians, many magistrates, lawyers, and men of science. M. Dumontpallier presided. M. Bernheim opened a discussion on the connection between hysteria and hypnotism; he combated the idea that the two conditions were identical, or even analogous, his main argument being founded on the large proportion of persons who can be hypnotized. He stated that he had been able to hypnotize sixty-nine patients out of seventy-two in hospital under his care for various diseases, and urged that it was absurd to suppose that so huge a proportion could be hysterical. M. Bérillon followed with the somewhat astonishing statement that almost all children could be hypnotized, except those who were idiotic or hysterical.

Human Vivisection.—Some three years ago Hahn, a Berlin surgeon, reported the experimental inoculation of six pieces of carcinomatous tissue taken from one breast of a woman and transplanted into the other breast. In fourteen days the grafts had united, and in four weeks the microscope showed the tissues about the transplantations to be carcinomatous. Strangely enough, this observation seems to have passed unnoticed and uncondemned even by those that are now very properly shocked at recent similar procedures.—*Medical News.*

Dr. Guillotin.—A pathetic picture is the horrible immortality of Dr. Guillotin. One of the most skilled sanitarians of his time; a pioneer in prison reform; a philanthropist shocked by the tortures of the public executioner, he sought to save pain by substituting the certainty of machinery for the uncertainty and resultant brutality of a swordsman. His name in its horrible fame is likely to outlive Cæsar's. Many sanitary reforms instituted by him still guide modern sanitation.—*Medical Standard.*

American Orthopedic Association.—The following is the programme of the Fifth Annual Meeting of the American Orthopedic Association, to be held in the Arlington Hotel, Washington, D. C., September 22, 23, 24 and 25, 1891. First Day, Tuesday.—"The President's Address," by Dr. A. B. Judson; "The Orthopedic Work of the Late Mr. Thomas," by Dr. A. J. Steele; "Uniform Nomenclature in Orthopedic Surgery," by Dr. W. R. Townsend; "Two Cases of a Peculiar Type of Primary Crural Asymmetry." by Dr. Henry Ling Taylor; "On the Best Means of Preventing a Loose Joint, or Dangling Limb, after Resection at the Shoulder-joint, with an Illustrative Case," by Dr. W. R. Whitehead; "A Case of Spina Bifida with Partial Motor and Sensory Paralysis, Double Equino-Varus and Purulent Bursitis," by Dr. H. Augustus Wilson; "Congenital Club-Foot, with Absence of Great Toe and Contiguous Bones of the Instep," by Dr. T. M. L. Chrystie; "A Case of Club-Foot, Club-Hand, and Multiple Joint-Deformity," by Dr. William E. Wirt; "On the Use of the Wrench in the Treatment of Club-Foot," by Mr. Robert Jones, of Liverpool; "Operation upon the Concave Surface in Talipes Equino-Varus," by Dr. B. E. McKenzie; "The After Treatment of Excision of the Knee-Joint," by Dr. John C. Schapps; "Gonorrhœal Rheumatism and Its Treatment, Primary and Secondary," by Mr. B. E. Brodhurst, of London; "Atrophy in Joint-Disease," by Dr. E. G. Brackett; "The Diagnostic and Prognostic Value of High Temperature in Chronic Joint-Disease," by Dr. Robert W. Lovett; "On the Tests for Recovery from Joint Disease," by Mr. Robert Jones; "Apparatus for Making Traction," by Dr. William E. Wirt; "Some Lateral Traction Fixation Hip-Splints," by Dr. A. M. Phelps. Second Day, Wednesday.—"Rachitis in Adolescence," by Dr. Bernard Bartow; "The Aspirator in Orthopedic Practice," by Dr. Ap Morgan Vance; "Congenital Misplacement of the Hip, with New Apparatus for its Treatment," by Dr. A. M. Phelps; "A Study of Atrophies," by Dr. Roswell Park; "The Diagnosis of Pott's Disease," by Dr. Robert W. Lovett; "The Differential Diagnosis in Pott's Disease," by Dr. George W. Ryan; "Syphilitic Pott's Disease in Children," by Dr. John Ridlon; "Pott's Disease and Pregnancy," by Dr. T. Halsted Myers; "Paraplegia in Pott's Disease," by Dr. E. G. Brackett; "Pressure-Myelitis in Pott's Disease," by Dr. Albert Hoffa, of Würzburg; "Abscesses in Pott's Disease," by Dr. Herbert L. Burrell; "Abscesses in Pott's Disease," by Dr. W. R. Townsend; "The Evacuation of Spinal Abscesses without Drainage," by Mr. George Arthur Wright, of Manchester, England; "Bilateral Lumbar Abscess, with a Case," by Dr. James K. Young; "The Benign Course of Abscesses in Pott's Disease under Efficient Mechanical Treatment," by Dr. Newton M. Shaffer; "The Value of Mechanical Treatment in Old and Neglected Cases of Pott's Disease," by Dr. Henry Ling Taylor; "The Mechanical Treatment of Pott's Disease, with an Exhibition of Apparatus," by Dr. A. M. Phelps. Third Day, Thursday.—"Malignant Disease of the Vertebræ Simulating Pott's Disease," by Dr. A. B. Judson; "Paralysis in Pott's Disease," by Dr. Charles L. Scudder; "Prognosis in Pott's Disease," by Dr. Samuel Ketch; "Proposed Treatment of Pott's Disease by Wiring the Vertebral Processes," by Dr. B. E. Hadra; "The Operative Treatment in Spinal Caries," by Dr. De Forest Willard; "The Treatment of Pott's Disease, with Especial Reference to the Early Stage," by Dr. Bernard Bartow; "Pott's Disease in Adults," by Dr. A. J. Steele; "Pott's Disease in Middle and Advanced Life," by Mr. Howard Marsh, of London; "Cervical Spondylitis," by Dr. L. A. Weigel; "The Prevention of Unnecessary Deformity in Pott's Disease," by Dr. Royal Whitman; "A Brief History of the Use of Suspension in Pott's Disease," by Dr. Benjamin Lee; "Recumbency in Pott's Disease," by Dr. Ap Morgan Vance; "Extension in Pott's Disease," by Dr. B. E. McKenzie; "Extension in Bed," by Dr. Charles C. Foster; "Traction and Fixation in Pott's Disease," by Dr. Reginald H. Sayre; "The Treatment of Pott's Disease," by Dr. V. P. Gibney; "Comparative Value of the Present Modes of Treatment of Caries of the Spine," by Dr. E. H. Bradford. Fourth Day, Friday.—"A Further Contribution to Typhoid Spine," by Dr. V. P. Gibney; "The Treatment of Congenital Dislocations of the Hip," by Dr. E. H. Bradford; "On Elongation of the Ligamentum Patellæ as a Factor in the Production of Certain Knee Troubles and Difficulties in Locomotion," by Dr. Newton M. Shaffer; "Observations on Torticollis, with Particular Reference to the Significance of the So-called Hæmatoma of the Sterno-Mastoid Muscle," by Dr. Royal Whitman; "Ten

Cases of Excision of the Knee-Joint for Disease, and their Lessons," by Dr. Joseph D. Bryant; "Rheumatic Spondylitis," by Dr. George W. Ryan; "The Definition and the Scope of Orthopedic Surgery," by Dr. V. P. Gibney; "The Relations of Lateral Curvature of the Spine and Flat Foot," by Dr. Paul Redard, of Paris; "Pathological Anatomy of Lateral Curvature of the Spine," by Dr. F. Beely, of Berlin; "Means of Recording Rotation in Lateral Curvature," by Dr. E. H. Bradford; "A Contribution to the Etiology of Lateral Spinal Curvature," by Dr. Charles L. Scudder; "Modifications in the Treatment of Lateral Curvature," by Dr. E. H. Bradford; "Spastic and Infantile Paralyses," by Dr. De Forest Willard; "The Operative Treatment of Spastic Paralysis," by Dr. L. A. Weigel; "The Operative Treatment of Spastic Paralysis," by Dr. Charles L. Scudder; "Additional Notes on Sacro-Iliac Disease," by Dr. Benjamin Lee.

Yellow Fever is reported to be epidemic again in Port au Prince, Hayti. Several of the crew of a French man-of-war in the harbor have died of the fever, and others are down with the same disease.

Pennsylvania Railroad Surgical Society.—A meeting of the surgeons to the Pennsylvania Railroad has been called, at Cresson, Pa., Thursday, September 3d, for the purpose of organizing the "Pennsylvania Railroad Surgical Society." Information concerning the proposed society may be obtained by writing to Dr. I. P. Klingensmith, of Blairsville, Pa.

The International Congress of Hygiene and Demography.—The seventh annual session of this association was opened by the Prince of Wales, in St. James's Hall, London, on Monday August 10th. There were nearly 2,500 delegates present in the hall at the opening, among them, according to the cable report, being Pasteur and Koch. In his opening address, the Prince of Wales referred to the need for deliberations, such as those for which his auditors had assembled, the need growing ever more pressing as new problems in hygiene appeared for solution by students of that most important science. The unhygienic conditions of factory life, overcrowding in the cities, and the neglect of sanitary laws in centres of dense urban population were all sources of danger to which the people were exposed. The removal of these sources of danger with the least possible interference with the rights of capital and the liberties of the people, was a problem to the solution of which many of the greatest thinkers of the age had devoted much of their time, and which yet remained to be solved. He was happy to say, however, that statistics showed a marked improvement in this direction, and this might safely be taken as an earnest of the increased good to be accomplished by scientists in the future. Tuesday's session was devoted chiefly to the discussion of rabies, and of the most common animal parasites communicable to man. On Wednesday the papers read dealt, for the most part, with diseases communicated to man through milk and animal food. Thursday was given up to a discussion of tuberculosis in all its various aspects, among those appointed to speak being Dr. Burdon Sanderson, of London, and Professor Bang, of Copenhagen. It was announced that the programme for Friday would include the consideration of infectious diseases communicated from the lower animals to man, and *vice versa*. Saturday was reserved for excursions to various points of interest in a hygienic way in and about London, and on Monday the closing session will be held in the University of London.

Dr. Massei to Dr. O'Dwyer.—Professor F. Massei, of Naples, publishes, in the *Medical and Surgical Reporter* of August 8th, an article on intubation in Italy, which, he says, he offers as the best homage he can pay "to the genius and ability of the distinguished inventor of intubation, Dr. O'Dwyer."

The Memphremagog Hospital Clinic is the name of an institution recently established in Newport, Vt., by the physicians of that place and of West Derby.

Tetanus Neonatorum destroys almost every child born in the island of St. Kilda in the West Hebrides. Not more than one child of twelve to fifteen born survives the second week. There is no physician on the island, but the resident minister has gone to Glasgow to induce someone to come to the relief of the fated infants.

A Bone-Shedder.—Dr. Bell, of Parrottsville, Tenn., reported the case of a woman who sheds her bones, and showed some of the specimens before the East Tennessee Medical Society (*Meaical Standara*). He said: "The patient is seventy-one years of age, seemingly in perfect health, a well-preserved woman of medium height, average weight, and normal in every other respect. Twenty-one years ago the exfoliation of bone began in her fingers, and has during the succeeding years continued until she has twice shed ulna and radius, humerus, scapula, and part of inferior maxillary. This shedding takes place spontaneously without pain, hemorrhage, suppuration, inflammation, or inconvenience. On one occasion when churning she shed the radius. There is no deformity, supination, pronation, extension, flexion, and circumflexion being perfect. The bones shed (about six hundred pieces) were, on careful inspection by the society, found to be entirely natural. She has given about one hundred pieces of bone away as souvenirs. The woman is conscious of the pending expulsion of a bone about ten minutes before it takes place, and a perfect bone is always left in its stead. The bone makes its way out, always on the posterior side, and the wound heals by first intention, though at the 'exit of the bones' were numerous small scars. She has always been in comfortable circumstances and is cheerful, a very interesting fact as showing the power of the mind to adapt itself to extraordinary circumstances."

Bequests to Charities.—By the will of the late Rev. C. W. Morrill, the House for Consumptives gets $5,000 and St. Mary's Hospital $5,000. By the will of the late David Stewart, St. Luke's Hospital gets $5,000. By the will of the late Isaac H. Frothingham, Brooklyn Hospital gets $2,000.

Tri-State Medical Association.—The third annual meeting of this Association will convene in Turner Hall, Chattanooga, Tenn., Tuesday, October 27, 1891, and continue in session three days. All who desire to read papers should send title before September 1st, to the Secretary of the Association, Dr. F. T. Smith, Chattanooga, Tenn.

Reviews and Notices of Books.

A Practical Treatise on Fractures and Dislocations. By Frank Hastings Hamilton, M.D., etc. Eighth Edition, Revised and Edited by Stephen Smith, M.D., etc., New York. 8vo, pp. 849. Philadelphia: Lea Brothers & Co. 1891.

Probably no treatise on special surgery has brought more renown to American medical literature than has the one now before us. Eight editions are its best commendation. The present editor was a pupil of Dr. Hamilton, and was largely concerned in the preparation of the original first edition. But science grows, and no matter how complete a book may be for its time, it needs periodical revision to enable it to hold its own against new-comers and to keep abreast of the times. Some famous old preachers used to say that they had to preach a sermon thirty or forty times, more or less, in order to get it into thoroughly proper shape. So a book of such a nature as Dr. Hamilton's has to be rewritten more or less completely every few years. In the present issue the text has been rendered more compact, irrelevant matter has been omitted, and a smaller size of type used in the narration of purely clinical matter. The illustrations are more complete, and the subject-matter brought down to our present knowledge. It still bears the original impress of conscientious regard for truth and of accuracy of detail. It seems to be that happy medium between a mere text-book and a collection of clinical cases. It is in a sense both, but the combination of didactic with clinical teaching which its pages illustrate is one rarely met with in such a perfect degree. Well can we appreciate the editor's remark, that his work has been a grateful service. "Hamilton on Fractures" will still continue to be, as it always has been, a "court of last resort" for those puzzling questions every person meets in treating this class of injuries.

A Treatise on Surgery. By C. W. Mansell Moulin, M.D., Oxon., Surgeon to the London Hospital. 8vo, pp. 1180. Philadelphia: P. Blakiston, Son & Co. 1891.

Dr. Moulin's work has partially been that of editor, as he has had the assistance of various writers on special subjects. Among these latter writers may be mentioned Hutchinson, Hovell, and Eve. Special attention is given throughout to treatment, and the discussion of controverted points on pathology, etc., is relegated to the background. The key-note is the "idea that the chief aim and object of surgery at the present day is to assist the tissues in every possible way in their struggle against disease."

From such a stand-point it goes without saying that the writer's attitude is a conservative one. He is, however, free from hesitancy, and shows a keen appreciation of the rapid strides of surgical art in the last decade. No less than two hundred of the illustrations were drawn expressly for this work. It has all the conciseness of Druitt's well known work, and the advantage of a somewhat more extensive description of certain conditions occurring in practical work. The book is creditable alike to author, assistants, and publishers.

A Practical Treatise on Diseases of the Skin. By Henry G. Piffard, A.M., M.D., Clinical Professor of Dermatology, University of the City of New York, etc. Assisted by R. M. Fuller, M.D. Pp. (10 × 14) 157. New York: D. Appleton & Co. 1891.

Probably in no department of medical literature has more creditable work been done by our local profession than in works on dermatology. The elaborately illustrated works of Fox and Morrow have met with a flattering reception, and to them is now added a third which well sustains its author's reputation. In accordance with its title, it deals almost entirely with the practical side of the question, and omits all discussion which would interest only the specialist. In the author's view our knowledge in regard to the pathological histology of the skin is in an extremely inchoate state, and he has therefore systematically omitted reference thereto.

The illustrations comprise fifty full page original plates, with thirty-three illustrations in the text. The plates are taken from photographs made by the author with the aid of artificial light, which he has found superior for this purpose to day light. Dr. Fuller has prepared the articles on Anidrosis, Dysidrosis, Ichthyosis, and Morphœa.

The first sixteen pages are devoted to general remarks on diagnosis and treatment. Then follows the description of the various skin affections. A good point is the fact that the plates are opposite the descriptive text, and not (as is so often the case in books of this kind) a few pages before or after. It will always be a disputed point whether skin lesions are more accurately depicted in tinted or untinted plates. These plates are untinted, but are accurate in every detail, reflecting great praise on the artistic ability of the author. Dr. Piffard does not claim for his book, that it contains all there is to be said on the subject; but that it does contain the fundamental principles illustrated in daily work, and that, too, clearly and concisely stated, no one can deny. It is essentially a working book. As such we welcome it and predict many editions. The concluding article deals in a brief, yet comprehensive, manner with the subject of Psorospermosis. Dr. Piffard regards the so-called Psorosperms not as animal parasites, as has been asserted by some writers, but as simple rete-cells undergoing a species of corneous degeneration. He regards the subject as one whose development is likely to cause great changes in theoretical dermatology.

Insomnia and Its Therapeutics. By A. W. Macfarlane, M.D., Fellow of the Royal College of Physicians, Edinburgh, etc. (From Wood's Medical and Surgical Monographs.) 8vo, pp. 302. New York: William Wood & Company. 1891.

The book opens with chapters on the general physiology of sleep-dreams, etc., with special detail on the conditions which influence sleep and sleeplessness. Then follow chapters on insomnia as caused by disordered states of the various bodily apparatus, as the nervous system (which naturally receives the greatest amount of attention), the alimentary tract, circulatory and respiratory systems, etc. Insomnia due to gout and to toxic agents, and habits of various kinds, receive each a special chapter. As is implied in the title, therapeutics have a prominent place, and many prescriptions are given which the author has found to be of service. A general discussion on bathing and electricity as applicable to the relief of insomnia, closes the volume.

A work of this kind, founded as it is on a scientific basis, has a most important mission in these days, when new hypnotics come along in bewildering profusion. The temptation now is for the careless practitioner to use somnal-hypnone and others of the class without any very clear conception of what their effects really are. Dr. Macfarlane does not ignore any aid of modern pharmacology, but his therapeutics are commendable in that they aim to remove causes rather than to merely relieve effects. The work is to be unhesitatingly commended.

Philadelphia Hospital Reports, Vol. I., 1890. 8vo, pp. 363. Edited by Charles K. Mills, M.D. Philadelphia: Detre & Blackburn. 1891.

The volume gives a history of the early and later days of that institution so widely known as the "Blockley" Hospital, and is of course of interest mainly to Philadelphia physicians. The other portions of the work describe the clinical results of the service in the various wards, histories of local epidemics, etc. Among the contributors are: Drs. Mills, Deaver, Dercum, Formad, Davis, and

S. Solis-Cohen. It is a most creditable production. It suggests most painfully the lack of any such publication from our New York hospitals, with their vast amount of clinical material; which might as well be in Jericho so far as doing any good to general medical knowledge is concerned.

CHILDBED NURSING. By CHARLES JEWETT, M.D. Pp. 40. New York: E. R. Pelton. 1891.

THE writer originally prepared this manual for the training-school in the Long Island College Hospital, in which institution he fills the chair of Obstetrics. It is the best work of its kind to put in the hands of beginners that we have yet seen, and we say this advisedly. The plan followed is that of statements in condensed paragraphs. Anyone who can read English and who has an ordinary amount of common sense can understand what is meant, and we take it that in a manual of this kind that is the criterion to go by. Dr. Jewett has made the way of obstetric nursing so plain that "the wayfaring man (or woman), though a fool, need not err therein."

THE POCKET MATERIA MEDICA AND THERAPEUTICS: A Résumé of the Action and Doses of all Officinal and Non-officinal Drugs now in Common Use. by C. HENRI LEONARD, A.M., M.D., Professor of the Medical and Surgical Diseases of Women and Clinical Gynæcology, Detroit College of Medicine; Member of the American Medical Association; of the Michigan State Medical Society; of the Wayne County Medical Society; Detroit Gynæcological Society, etc. Detroit: The Illustrated Medical Journal Co. 1891.

THIS is a convenient little work of reference for the busy man who wants to refresh his memory, or gratify his curiosity, concerning the origin, dose, and medicinal properties of any drug, and has not much time to do it in. The work is rather one of materia medica than of therapeutics, very little space being given to the latter department. The different drugs are treated of in alphabetical order, the officinal ones under their pharmacopœial names, and the non-officinal under their scientific names if they have any, otherwise under the designation by which they are generally known. The value of the book as one of reference consists in great measure in its completeness, many of the newer remedies being included, a description of which would be found elsewhere only after laborious search. This value would, however, be greatly enhanced by the addition of an index of the English names of the drugs and of the plants from which they are derived.

A TEXT-BOOK OF PRACTICAL THERAPEUTICS, WITH ESPECIAL REFERENCE TO THE APPLICATION OF DRUGS TO DISEASE AND THEIR EMPLOYMENT UPON A RATIONAL BASIS. By HOBART AMORY HARE, B.Sc., M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Laureate of the Royal Academy of Medicine in Belgium; of the Medical Society of London; Fellow of the American Association of Physicians; of the American Society of Physiologists; Secretary of the Convention for the Revision of the United States Pharmacopœia of 1890. Second Edition. Philadelphia: Lea Brothers & Co. 1891.

IT is not often that the second edition of a medical textbook appears within eight months of the first, and the fact that such is the case with the volume before us bears stronger testimony to the excellence of the work than could anything that might be said of it in a brief notice. In the notice of the first edition, in January of this year, we described the general plan of the work, which is a thoroughly practical one, and moreover one that permits of easy reference to any drug or the treatment of any disease concerning which the reader seeks information. The author has taken the opportunity of the appearance of a new edition to revise the work, adding some new drugs and discussing some others more fully, and has also introduced a notice of the rest cure, and the treatment of spinal affections by suspension. The book is one that can be confidently recommended to any, students and practitioners alike, who may desire a practical and reliable guide to modern therapeutics.

PRIMER CONGRESO MEDICO REGIONAL DE LA ISLA DE CUBA, CELEBRADO EN LA HABANA EN ENERO DE 1890. Habana: A. Alvarez y Ca. 1890.

THE first Cuban Medical Congress was evidently a great success. Many excellent papers were read, and there was a large attendance of practitioners from different parts of the island. The volume of transactions before us is a large octavo of nearly six hundred pages, filled with original communications read before the Congress and with the discussions upon them.

COLLECTED CONTRIBUTIONS ON DIGESTION AND DIET. By SIR WILLIAM ROBERTS, M.D., F.R.S. Formerly Physician to the Manchester Royal Infirmary, and Professor of Medicine in the Victoria University. Pp. iv. 261. Philadelphia: Lea Brothers & Co.

THIS volume consists mainly of a reprint of two publications by the author—namely, the Lumleian Lectures on the "Digestive Ferments and Artificially Digested Food," delivered before the College of Physicians in 1880, and a course of five lectures on "Dietetics and Dyspepsia," given at the Owens College in 1885. These two books ran through two editions, and there still being a demand for them, the author has printed them together and added five other lectures on kindred subjects. The volume therefore embraces all the distinguished author has written on Digestion, Dietetics, and Dyspepsia, in which subjects he is the acknowledged leader of the age. To him more than to any other man belongs the credit of bringing artificially digested food to its present favor with the profession. His lectures are of great value and interest, and the work in hand will be warmly welcomed by physicians.

A TREATISE ON THE DISEASES OF THE NERVOUS SYSTEM. By WILLIAM A. HAMMOND, M.D., Surgeon-General United States Army (Retired List). Late Professor of Diseases of the Mind and Nervous System in the College of Physicians and Surgeons of New York, the Bellevue Hospital Medical College, the University of the City of New York, and the New York Post-Graduate Medical School and Hospital, etc.; with the collaboration of Græme M. Hammond, M.D., Professor of Diseases of the Mind and Nervous System in the New York Post Graduate Medical School and Hospital, etc. With one hundred and eighteen Illustrations. Pp. 932. Ninth edition, with corrections and additions. New York: D. Appleton & Co.

TO criticise Dr. Hammond's work on Nervous Diseases would be as useless as to criticise Gray's Anatomy. Everybody in the profession knows what it is. It made its first appearance twenty years ago, and immediately took the front rank of all books of its kind in the English language. It was soon translated into French, German, and Spanish, and became in time the vade mecum of neurologists of all nations. It deserved its success. It was complete, and from a scientific stand-point far in advance of the times. It had the meat and the facts in it that one could store away and use. No book was ever more popular with teachers and students as a text-book. In addition to all of these good qualities, it was and is exceedingly readable. Dr. Hammond is a master of the English language, and his treatment of his interesting subject makes a book that even the layman can enjoy. In the twenty years that have elapsed since its first appearance the book has run through eight large editions. There is still a demand for it, and the present edition, which is a big improvement on all others, is issued to meet that demand. The author's investigations in the field of the circulation of the nervous system made him

famous years ago. He continues them here, and the chapters on Congestion and Anæmia of the Brain and Cord in this edition are more complete than ever before. Many scientific men consider his position an untenable one and his arguments imaginary, but nevertheless he explains many symptoms and conditions that are otherwise inexplicable, successfully treats them, and is upheld by men like Broca, Lombard, and Krishaber. The chapters on Inflammation of the Spinal Cord, Epilepsy, Plumbism, and Alcoholism are also worthy of special praise. The present edition, with the assistance of the author's son, has been brought up to the present time. There are many additions, noteworthy among which are several excellent illustrations.

THE GENUINE WORKS OF HIPPOCRATES, Translated from the Greek, with a Preliminary Discourse and Annotations, by FRANCIS ADAMS, LL.D., Surgeon. Octavo, 766 pp., extra muslin, gilt top. New York: William Wood & Company. 1891.

IT is not often that a physician, who is a bibliophile as well, can gratify his taste for handsome books, and at the same time keep within the limits of professional study. Editions de luxe of medical works are rare, yet they ought not to be, for we have old masters in medicine, and classical writings which are worthy of tender treatment at the hands of the printer and bookbinder. Hippocrates, of all the physicians of antiquity whose names have been preserved to us, is the best known and the most celebrated, and it needs but a hasty glance through his writings to show the reason why his fame has come down through the ages and has lived along with that of Socrates and Æschylus and Aristophanes and Pindar, and others of his contemporaries. One may not learn a great deal that is practically useful from these pages (and again, if he reads them understandingly he may learn much), yet he will be a sounder man and a more cultured physician, his views will be broadened and his wits sharpened by his perusal of the writings of the master. We know of no better leisure reading for the doctor, and withal the outward appearance of the book is as refreshing to the eye as are its contents to the mind.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS, Vol. X., No. 3. Contents: "Influenza Associated with Nervous and Mental Diseases," by DR. VAN DEVENTER. "Technique of Ling's System of Manual treatment as Applied to Surgery and Medicine," by ARVID KELLGREN, M.D.; "Antipyresis," by PROFESSOR DR. ARNALDO CANTANI; "Some Urinary Disorders Connected with the Bladder, Prostate, and Urethra," by REGINALD HARRISON, F.R.C.S.

THIS volume of the "Monographs," for June, 1891, is in line with preceding numbers as regards the interest and practical utility of the different papers. The first article is a careful study of the effects of influenza upon the patients in the wards for nervous diseases, at the Binten Hospital in Amsterdam. The paper on Ling's method of massage contains the lectures delivered at the request of the surgeons of the Imperial and Royal Austro-Hungarian Navy. These interesting chapters, illustrated by seventy-nine cuts from photographs, make up the bulk of this number. "Antipyresis," by Professor Cantani, is an interesting study of the subject. And the volume closes with the short but valuable paper by Mr. Harrison.

A Druggist's Slight Error.—Customer: You made a mistake in my prescription the other day. It called for ten grains of opium, and I got a small package containing magnesia.

Druggist: Are you sure about it?

Customer: Yes; here is a duplicate prescription from the physician. Now the question is, who got the opium?

Druggist: Dear me, that's so; (to the prescription clerk) James, who's dead in the neighborhood?

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Fifty-ninth Annual Meeting, held at Bournemouth, July 28, 29, 30, and 31, 1891.

(From our Special Correspondent.)

FIRST DAY, TUESDAY, JULY 28TH.

The Town of Bournemouth.—The fifty-ninth annual meeting of the British Medical Association commenced here to-day. Bournemouth is of comparatively recent growth, and the Association holds its annual meeting here for the first time. The town is one of great interest to the medical profession, as it has come very much to the front within recent years as a health resort; hence its extremely rapid expansion. It possesses several great natural advantages. Situate in a bay on the south coast, it is but a little more than a hundred miles from London, and an excellent train service renders it possible to reach the metropolis in about two hours and a half. The town consists of a valley in the centre running back from the sea, and rising gradually on either side to the level of the cliffs. The greater part of the valley is laid out as a public garden through which a small stream finds its way down to the sea. The town is built partly in the valley, but the greater part of it is located on the higher ground on either side. The East and West Cliffs contend in friendly rivalry for the honor of being the most salubrious region of the town, while the inhabitants of the valley maintain that their part of the town is at any rate more sheltered than either. The most recent extension of the town is westward, but the East Cliff is more thickly covered with pines, which, however, pervade more or less the whole district. The soil is sandy in most parts, and Bournemouth has the reputation of being an extremely dry place. That may be the case as regards the soil, but, considering the abundant vegetation, it can scarcely be said that the air is excessively dry, though a dry atmosphere used formerly to be enumerated among the special virtues of Bournemouth. To-day, however, its candid friends admit that the town is not specially suited for rheumatic patients. It is for phthisis and thoracic affections generally that Bournemouth is now chiefly recommended. The air is mild and, to some, even depressing. The pines give a certain amount of shelter from the winds and some fragrance to the air. London fogs do not appear here, though a "sea-mist" is occasionally seen. There are no noisome manufactories to pollute the air, and the latter is much more fresh than in most towns, owing to the fact that the houses are scattered over a large area instead of being closely aggregated together. Many of them are detached and have large gardens—even those which are used as lodging-houses and boarding houses. Houses at Bournemouth are dear and the cost of living high. It is, therefore, more suited to the upper classes than to those with moderate means. Medical men get good fees, and few dispense their own medicines. There are about eighty doctors, though the population (excluding visitors) is only about seventeen thousand.

Bournemouth possesses no municipal buildings at all corresponding to the reputation it has attained. The meetings of the Association are therefore held somewhat under difficulties, the work of the sections being carried on in several separate buildings scattered about the town. The first general meeting took place this morning, when Dr. Wade, the retiring President, occupied the chair, only, however, to vacate it in favor of Dr. J. Thomson Roberts, the President-elect. After the usual vote of thanks the President of the Council moved the adoption of the annual report of the Council. It appeared from this that the Association had continued to increase, and that the present number of members was 13,861, being 501

more than at the corresponding period of last year. New branches had been formed, and the finances were in a satisfactory condition. The reports of the various committees were then presented in due order. In the afternoon a choral service was held at St. Peter's Church, when a sermon to the members of the Association was preached by the Rev. Canon Wilberforce.

Address of the President.—At the evening meeting Dr. Thomson delivered his presidential address. After bidding the members a hearty welcome he proceeded to speak of the town in which they were assembled.

A New Health-resort.—A few years ago, he said, Bournemouth would not have been large enough for their annual meeting. There were those among them, by no means very advanced in years, who could remember when it was little more than a village, and when the nearest railway station was twelve miles off. The growth of Bournemouth was due to several causes. In the first place, the result of residence here during the winter and spring months had been so satisfactory that invalids had returned winter after winter, and had brought their friends. Then people had made the discovery for themselves that, though a mild winter climate, Bournemouth was also a delightful summer climate, and thus there was a steadily progressive summer season. When he first knew the town, said Dr. Thomson, the summer season was very small. "Go to Bournemouth in July! why, you could cook chops in the sand," was the exclamation which would be made. But people now knew that this was the reverse of the truth, that it was in reality a cool and bracing seaside change—for the south coast—in summer. In the third place, care had been taken to preserve, and when possible to improve, the natural advantages of the district. Bournemouth had many attractions for the geologist, for the botanist, and for the antiquary. Dr. Thomson said that, relatively to the amount of labor which had been bestowed upon other branches, that which had been bestowed upon medico-meteorological researches might be described as meagre, and much further research was necessary. The climate of Bournemouth was influenced by the geological formation on which the town was built, by the geographical position, and by the pine woods which surrounded the district. Persons must not, of course, expect too much. They had not left England, and so must be prepared for the uncertainties of an English climate. There were classes of cases for which Bournemouth was not suitable and who did not get on well here. Bronchial cases with very irritable throat, which required a moister and more soothing climate, were better elsewhere. Many throat cases, with very irritable mucous membrane, also did better in moister climates, and away from the sea. And there were some forms of neuralgia which seemed to be aggravated either by dry air or the proximity to the sea. But this short list nearly exhausted the forms of invalidism which might not receive benefit from a sojourn here. When he first began work in Bournemouth a very large majority of the patients one saw were cases of lung trouble. Now he saw persons broken down in health from every possible cause, and, even with an extended experience, he did not feel called upon to enlarge the list of cases unsuitable.

After referring to the medical institutions of Bournemouth, Dr. Thomson concluded his address by discussing at some length the present position of medical officers of health in England, and the working of the most recent legislation in this matter as found in the Local Government Act of 1889.

Second Day, Wednesday, July 29th.

Address in Medicine.—At the second General Meeting, held this afternoon, the address in Medicine was delivered by Dr. T. Lauder Brunton, F.R.S., of London. Dr. Brunton commenced his address by remarking that when friends met again, they invariably began to speak of the changes that had taken place since they parted. Twenty-five years ago their president and himself occupied adjacent rooms as resident officers at the Edinburgh Royal Infirmary.

A Quarter of a Century, and its Changes.—Perhaps there was no period in medicine in which more changes had occurred than during the twenty-five years which had since elapsed. Great changes had taken place as regarded the medical student. Previously to 1861 it was easy for anyone to become a medical student, however idle he might be, but in that year the General Medical Council instituted a compulsory preliminary examination. Two classes of students were colleagues with their president and himself, viz., those who had not passed a preliminary education, who were called the "old statutes" men, and those who had passed a preliminary examination, who were termed "new statutes" men. The "old statutes" students were rather a mixed assemblage; some were industrious, some were idle, and some, he was afraid, were disreputable. Among the "new statutes" students, there was a smaller proportion of idle men. Among the "old statutes" men, the subsequent struggle for existence was very severe; it was less severe among the "new statutes" men, by reason of the unsuitable men having been weeded out at the preliminary examination. The "old statutes" men comprised many who ought never to have been allowed to enter, and the weeding out process proceeded during life. This action on the part of the Medical Council had, by raising the status of the profession, caused more men to enter it, and thus led to its being more overcrowded. Increased numbers tended to the degradation of the profession, as it was rendered more difficult to get a living, and doctors were sometimes tempted to think more of their fees than of their patients. At first, however, the new regulation had a salutary effect. There had also been a change as to the education of the medical student. A doctor had to do much more now than to look at a patient's tongue and feel his pulse. He had not only to learn auscultation and percussion, but he had to study histology; he had to learn not only how to recognize tubercle bacilli under the microscope, but how to stain and examine them.

Changes in Disease.—There had also been changes in disease. Apoplexy was formerly said to be common; it was really rare and many cases used erroneously to be called apoplexy when they were not. Cancer was now said to be increasing; probably it was not really so but our increased power of diagnosis enabled us to detect many more cases than formerly. Our increased knowledge of medical chemistry enabled us to diagnose many cases of kidney disease which would formerly not have been recognized. But there were also real, as well as apparent, changes in disease. Typhoid fever was more common now than formerly because improved drainage disseminated the disease. Typhus, on the other hand, was less common. When he first met Dr. Thomson, at Edinburgh, the latter was constantly wearing a smoking-cap because he had had his head shaved in the course of an attack of typhus. Shortly afterward, one of the physicians and two of the house-physicians to the infirmary died, while another house-physician just escaped with his life. At the end of the year (1867) there were nearly one hundred and fifty patients in the hospital at once. The disease was stamped out a few days later when a certain close leading to the Cowgate, and which had been a hot-bed of fever, was pulled down to make way for the new University Building. Pyæmia, again, was now less common—thanks to Lister and antiseptics.

The greatest advances had taken place in nervous diseases and in fevers. If he had to describe in one word the advance which had been made he would say "fevers," though, thanks to Ferrier and localization, much more was now known about nervous diseases. As to fevers, we now knew that they were due to the introduction of disease-germs; we knew the life history of these germs and how to cultivate them. Now, everyone had a thermometer in his pocket. It was only toward the end of

his career as a student that the thermometer came to be used, and then a clinical thermometer was a foot long and had to be carried about under the arm in a case! In his time at Edinburgh, Dr. Hughes Bennett said he had revolutionized the treatment of pneumonia by substituting bleeding for feeding. One day, however, a man came into Bennett's wards whom he could not thus cure. The man was comatose—dying. Bennett was very angry. A Swede who was present asked Bennett's permission to treat the patient and, having received it, proceeded to dip rags in cold water and apply them to the patient. Dr Brunton going to see the patient after a short time found him sleeping placidly. Anyone now using a thermometer and finding it marked 107° F., would cool the patient down. It was, indeed, not necessary to have it done by the medical man, for directions could be left with the nurse.

Little Things Often Lead to Great Results.—The speaker instanced many exemplifications of this adage. The history of antipyretics, he said, could be traced back to the cupidity of the Spaniards of the Cordilleras. They cut down the cinchona trees to sell the bark, and did not plant others. Quinine became so dear that it became evident that anyone who could make it artificially would make his fortune. Among others, Perkins tried, and though he did not succeed in making quinine he discovered the aniline dyes. We used these in histological work, and without them many of the bacilli would have defied detection. The impulse thus given to the study of the aromatic compounds led to the production of salicylic acid and acetanilide, antipyrin, phenacetin, and all the other antipyretic remedies whose number was probably legion, and whose formulæ were bewildering. Thus good came out of evil and, as St. Paul said, the foolish things of this world confounded the wise. Why did tartaric acid sometimes crystallize in one shape and sometimes in another? This might be thought to be a foolish question, but it had led to all Pasteur's researches, and by saving the wine trade of France and preserving the herds of cattle, he had enabled his countrymen to obtain the large sums which they had paid to the Germans as a war indemnity. Pasteur noticed that tartaric acid sometimes turned the ray of polarization to the right, sometimes to the left; that, indeed, there were two crystals apparently alike, but really different; and that these could be combined so as to form a symmetrical crystal having no power of rotation. This led him to look to life and living beings as the source of asymmetry. He tried to produce this asymmetry in salts of tartaric acid by fermentation, and found that during the process an organism developed which ate up the dextro-tartaric acid and left the lævo-tartaric acid behind. This led him to investigate such minute organisms, and he showed that most processes of fermentation were due to their presence. The two views of the action of ferments—namely, the chemical and the biological—might be likened to Pasteur's two kinds of tartaric acid, each by itself being lop-sided and incomplete, and forming a symmetrical whole only when united. There could be no doubt that diastase was not a living organism, and yet it converted starch into sugar. There could be as little doubt of the biological view that yeast and other organisms which caused fermentation were living bodies, and that without their presence alcoholic, acetic, and other forms of fermentation would not exist. We had recently come to recognize that these living organisms might produce their effect by manufacturing chemical ferments, and that these ferments might occasionally do the work, though the organisms which formed them were absent. It was true that it was difficult, perhaps impossible, to get fermentation from the dead yeast plant, but we might find a parallel for this in the fact that the pancreas of the higher animals sometimes yielded an active ferment and sometimes not. We need not wonder that the ferments produced by microbes had but a slight action compared with that of the microbes themselves, if we remembered how little power of digestion a dead pig's stomach had compared with that not only of the live animal itself, but of the herds of swine consisting of its "fathers and mothers, its brothers and sisters, its cousins and its aunts." In the process of fermentation microbes were growing, fermenting, and dying with great rapidity, and many generations occurred in a fermenting fluid in the space of a few hours, so that the total effect they produced would be out of all proportion to any which could be got from the microbes themselves at a single instant.

Micro-organisms and Disease.—From organisms as a cause of fermentation, and of the diseases of wine and beer, Pasteur went on to investigate their action as causes of disease in living beings—first, in the silkworm, next in the lower animals, and lastly in man. He established the dependence of the silkworm disease and of anthrax upon the presence of specific microbes which could be transmitted and communicate the disease, and by destroying the infected eggs of the silkworm he eradicated the disease and restored the silk industry to France. Pasteur then found that disease-germs could be grown outside the body and, under certain conditions, their virulence be reduced; the virus thus weakened could be again rendered potent by successive animal inoculations. Koch's method of "plate cultivations" enabled us to separate the different germs.

Dr. Burton went on to say that there was a struggle for existence among microbes, and also between microbes and the organism. The struggle for existence between the cells of an organism and microbes had been beautifully shown by Metschnikoff, in the daphne, or water-flea, where the process of the cells eating up the microbes or the microbes destroying the cells could be actually observed under the microscope. This process of phagocytosis was now regarded by many as only a small part of the struggle between an organism and a microbe, but it was impossible to see one part of a microbe half digested by the cell in which it was imbedded, while the part outside remained unaltered, without believing that the process was one of great importance.

Within the last few years attention had been gradually becoming directed less to the microbes themselves, and more to chemical investigation of the ferments which they produced. It was now possible to separate the albumoses and poisons from the microbes which produced them. As the albumoses produced by microbes were nearly allied, chemically and physiologically, to those formed in the alimentary canal of the higher animals by the digestive ferments, it was natural to suppose that microbes, like the higher animals, split up proteids, starches, and sugars by enzymes, which they secreted, and which in both cases might be obtained apart from the living organisms which produced them. The albumoses produced by microbes resembled those formed during normal digestion in being poisonous when injected directly into the circulation, though they might not be so when absorbed from the intestinal canal. Woolridge found that the thyroid and thymus glands yielded a proteid which coagulated the blood and caused instantaneous death; while Schmidt-Mühlheim, working under Ludwig's direction, found that peptones had an exactly opposite effect, and prevented coagulation altogether. This was something like Pasteur's two kinds of tartaric acid, for here we had two bodies, one of which destroyed coagulability, the other increased it, while many albuminous bodies had no action on coagulation whatever. Dr. Brunton quoted an illustration which he had used elsewhere. Albumin, he said, might be compared to a glass. Split it in two and it became harmful; join the broken halves and it became harmless again. Microbes might have this action on albumin in the organism. If one-half of the resulting products were destroyed in the organism, we could not reunite them, but it might be possible to get the other half from elsewhere.

Artificial Immunity against Disease.—Dr. Brunton then referred to the observations of Hankin, who found

that a few drops of rat's serum injected into a mouse rendered it as insusceptible to anthrax as the rat. Working on similar lines, Bernheim and Lepine had used the injection of goat's blood in phthisis, and Richet had used the serum of dog's blood. If immunity could be insured by such slight changes in the organism as a few drops of serum from a rat would produce in the body of a mouse, it was natural to suppose that a similar change might be effected by removing the albuminous substance from one part of the body and introducing it into another after it has perhaps undergone slight change. Experiments on animals had also shown that withdrawal of blood from the veins caused absorption of proteid matters from the tissues, and these might have an action of their own upon the blood and tissues generally with which they were brought into contact. Free purgation might have a similar action.

Antisepsis and Disinfection.—Speaking of antiseptics, Dr. Brunton said the Good Samaritan was the first to practise antiseptic surgery. In more recent times wine had been recommended as an antiseptic application. The leeches of the Middle Ages used various substances to apply to wounds, among them being Friar's balsam, which was an antiseptic, but irritating. They evidently thought it was the irritation which did good, for they made their applications more and more irritating. On one occasion Paré's ointments ran out, and, finding his patients did as well without them, he abolished their use. Antisepsis went away till Lister came, and he did not seek for irritants. The recent triumphs of brain surgery which Mr. Horsley had achieved, would have been impossible without Ferrier's localization, and would have been equally impossible but for Lister's antiseptic method.

Dr. Brunton then spoke of disinfection, the prevention of epidemic diseases, the antivivisection movement, and the gains from experiments on animals, and the future of pharmacology. He then adverted to the training of medical students, and said they should be so trained as to enable them to keep abreast afterward with medical progress. This could only be done by giving them a thorough grounding; and this training must be of a practical nature, not only in the way of demonstrations, but of actual work on the part of the student himself.

THIRD DAY, THURSDAY, JULY 30TH.

The Address in Surgery was delivered this afternoon by PROFESSOR CHIENE, of Edinburgh. Professor Chiene said he wished to take John Hilton as his hero, and as his subject, "Rest as a Therapeutic Agent in the Cure of Surgical Ailments."

The Surgical Value of Rest.—Professor Chiene said he would speak of simple things as illustrating this. He would not attempt to define rest, or its opposite—unrest. Rest had a bodily and a mental aspect. We all knew it was not work, but worry—mental unrest—which killed, and a person would bear much physical discomfort to be relieved from it. Operations for cancer were often unsatisfactory, but they often gave mental rest to a patient by letting him think that no stone had been left unturned. There was a class of cases—syphilophobia, cancerophobia—in which the whole disease was psychic. A patient confined to bed often suffered as much from mental inactivity as from disease. The prescription, "Don't worry," might with advantage be burnt, and "Do some work" take its place. He had seen patients suffering from aneurism who had shown decided improvement by encouraging them to do some light mental work. In diagnostic incisions we had a valuable means of avoiding mental unrest.

He would not dwell on anæsthesia as a cause of rest except to say that he still held that chloroform was the best anæsthetic; as a pupil of Syme, he felt proud that the Hyderabad Commission bore out the views of that far-seeing man. Cocaine was of great value as a local anæsthetic in adults. We must take care to employ a pure solution and not to inject it into a vein. He used it either as a solution of salicylate of cocaine, or kept in pellets, and dissolved when required in camphor-water or distilled water; he never injected more that half a grain. In passing bougies, in phimosis, in tracheotomy, in fissure, and in simple cases of fistula in ano, in excision of tonsils, before injecting iodine in hydrocele, in small wounds of the face before stitching, he had found the drug valuable—also, used in the form of a bougie, to prevent urethral fever. He allowed four minutes to elapse after injection before operating. Pain given to a patient was a cause of mental unrest and led to the loss of confidence between patient and surgeon; this was especially the case with children. In the dressing of a wound the avoidance of movement was all important, and in this connection he could speak very confidently of the value of the many-tailed bandage. When writing this portion of his address he counted one day when going round his wards the number of patients with this form of bandage on after operation; there were ten. In fracture of the pelvis the many-tailed bandage was infinitely preferable to the ordinary roller. A frequent cause of local unrest in wounds, and of the free serous oozing which accompanied it, was the use of unnecessarily strong antiseptics. Some years ago, a smart writer in a journal, said "Lister's arguments are getting stronger, his solutions are getting weaker." He would have been nearer the truth if he had said, "His arguments are getting stronger, because his solutions are getting weaker." Asepticism was taking the place of antisepticism. The main danger of contamination was from what was directly put into a wound (dirty instruments, etc.) rather than from what fell into it.

Another aspect of Hiltonism was the use of absorbable drains, so that dressing of the wound was not required in order to remove the drain. Leaden splints steadied limbs after amputation and excision; shape the splint so that it can be unfolded without moving the limb. Apply your pressure firmly, but always leave a distal portion of the limb exposed, so that if it swells then the pressure is overdone and the bandage loosened. Horsehair stitches were valuable as combining rigidity and elasticity. The value of extension in fractures of the lower extremities was acknowledged; we must take care it was not overdone. It was not sufficiently often used in fractures of the upper extremity or after excision of the elbow or knee. In fractures, injuries, and diseases of the spine, in sacro-iliac disease, and in fractures of the pelvis, the use of double extension was of undoubted value. On the arrest of hemorrhage, Dr. Milne Murray had explained the action of hot water and shown that the general shock and the local reaction were much less than with cold water; this well illustrated rest.

Professor Chiene gave several examples of the value of rest in rectal and vesical surgery. Gradual dilatation of the sphincter ani before operations gave rest after the operation, as it was followed by a temporary paresis In colotomy, the inguinal region was preferable to the lumbar, because mental worry was avoided by making an artificial anus in a situation which the patient himself had under command. Rest could be given to the bladder by fixing in it a gum elastic catheter (taking care that the eye of the instrument was just within the cavity), and attaching to the catheter an India-rubber tube which passed into a vessel at the side of the bed. If the tube passed under water, and if the instrument and tube were full of fluid, there would be a siphon action which would remove the water from the bladder as it passed from the ureters. About a foot of fall was generally sufficient to keep the bladder empty; if the fall was too great, the mucous membrane was apt to be sucked into the eye of the instrument causing pain, and a stoppage of the outflow—the bladder filling with urine.

In tracheotomy, Hilton pointed out the value of rest to the inflamed larynx. In the treatment of cut throat, if we performed tracheotomy at once, and accurately united

the wounded surfaces, we obtained more rapid healing, because the wound was not used as a funnel through which air passed to the lungs. In using a bandage for varicose veins, it should be applied before the patient gets out of bed, and taken off after he is in bed, so that the veins do not fill; the same rule should be followed in the application of a truss. Continuous gentle elastic pressure would often act most efficiently, painlessly, and restfully in reducing an irreducible hernia, a prolapse of the rectum, or a paraphimosis.

Rest not Always Advisable.—In concluding, Professor Chiene said he wished it to be understood that there was another side to the picture. Harm might be done from too prolonged rest. Mechanical rest must also, in some cases, be interfered with to obtain physiological rest. Massage interfered with mechanical rest but it often got rid of effusions and relieved physiological unrest. It was a question whether we should not apply gentle massage in all fractures, so long as we could do so without displacing or causing movement between the broken fragments of the bone.

FOURTH DAY, FRIDAY, JULY 31ST.

Address on Public Health.—The concluding address was delivered this afternoon on Public Health by DR. EDWARD SEATON, Lecturer on Public Medicine at St. Thomas's Hospital, London. Dr. Seaton selected for his subject the Evolution of Our Sanitary System. The Public Health Act of 1872, he said, marked an era. Previously to that period medical officers of health were fewer and they were looked upon as mere sanitary referees to give advice when asked for. In 1872 their sphere of action was much enlarged. Many large towns—especially in the north—appointed medical officers of health, and their position was no longer that of mere sanitary referees. These appointments secured the continuous influence on the side of sanitation of men with a scientific and medical education It used to be argued that it was not necessary that a medical officer of health should give his whole time to sanitary work.

Many very valuable reports were issued soon after the passing of the Public Health Act, such as those on unregistered deaths, cemeteries, etc. Legislation took place with reference to the construction of new houses. Before 1872 many of the older and poorer parts of our towns were mere rookeries. From 1873 to 1883 many local Acts of Parliament were passed, laying down conditions for new houses to be built as to site, light and air, the prevention of dampness, and the provision of proper drainage. In this respect London was very far behind many provincial towns; for example, the erection of such lofty blocks of model dwellings as there were in some parts of London, would never have been allowed in some provincial towns—even where the price of land was as high as in London. The Model By-Laws of the Local Government Board were very good, but it was useless to have model by-laws unless they were adopted and provision made for enforcing them. By the Public Health Act medical officers of health were made responsible to the Local Government Board. Dr. Seaton sketched the characteristics of an ideal medical officer of health and said that the office should confer dignity in order to secure a competent and efficient officer.

The Acts for the Notification of Infectious Diseases were at first local. Compulsory notification was applied to London in 1889 and, since then, had been pretty generally adopted throughout the country. This result was an example of the far-reaching effect of what was at first a local tentative measure, and also of the effect of medical influence. The chief value of the Acts was that they enabled the authorities to wage war with the causes of infectious diseases. Notification was only useful as a means to an end, and its usefulness depended on our knowledge of the causes. In small-pox cases, the authorities could enforce the existing laws as to vaccination, provide for re-vaccination, and make provision for the segregation of patients. In cases of typhus, arrangements could be made for the isolation of patients, and for sanitation to be carried out in the infected districts. In scarlet fever and diphtheria local inquiries could be made, school attendance limited, and hospital accommodation provided. Notification afforded the authorities early and complete information of the rise of an epidemic, enabled them to use the powers of the Public Health Act; drainage could be attended to, schools controlled, and food and water supplies dealt with. Notification could not produce any results except where there was a good sanitary authority, an efficient medical officer of health, and good hospital accommodation for isolating patients.

Twenty-five years ago there were hardly any epidemic or isolation hospitals. In London there were only the Small-pox Hospital at Highgate and the Fever Hospital in the Liverpool Road. This was altered by the Metropolitan Poor Act of 1867—an Act largely due to the work of several members of the British Medical Association—and isolation hospitals began to be established. Before long, said Dr. Seaton, there will be no large town without its isolation hospital for infectious diseases. By a wise provision these hospitals were made free to all classes. If the order of the relieving officer had been made a badge of admission, it would have prevented many patients from applying to them. In London, the Metropolitan Asylums Board was the authority for providing isolation hospitals. The position of this Board was largely altered by the institution of County Councils in 1888. It was intended that the County Councils should eventually become the chief sanitary authorities, and no doubt they would in time. In the meantime, they might take up that part of sanitary work which related to the establishment of isolation hospitals.

Dr. Seaton thought the work of the Metropolitan Asylums Board might with advantage be transferred to the London County Council; we should thus have one sanitary authority instead of two. County Councils might, he thought, take up that part of sanitary work which was best vested in central authorities; there need be no interference with the principle of local self-government. There was not much to be said with regard to future sanitary legislation. Isolation arrangements should be transferred from the Poor-Law to the Health authorities. Any further evolution ought to be in the direction of greater simplicity and uniformity in the size of administrative districts and the methods of administration. In some of the small districts at present a medical officer of health only received ten pounds a year. Still he did not advocate the mapping out of the whole country into districts of uniform size, for cast-iron rules were bad.

The meeting concluded with the usual votes of thanks. Next year the Association is to meet at Nottingham. The Bournemouth gathering has been on the whole highly successful. Doctors and townspeople have been both hospitable and courteous to the numerous members and visitors—about eight hundred in all—gathered from all parts. It is to be regretted, however, that complaints have been made of discourtesy on the part of some of the permanent paid officials of the Association.

Beer versus Wine.—An investigation was recently made in Munich to ascertain the effects upon the health of excessive beer drinking. The men and women who keep beer places in Munich, as the heaviest beer consumers in the world, were the subjects of such a medical investigation last spring. The average lifetime of persons in Munich who pass the twentieth year in good health is fifty-three years. The average lifetime for proprietors of beer saloons, is 51.35; proprietresses of beer saloons, 51.95; brewers, 42.33. In the same city inquiry has shown that the male proprietors of wine rooms live but forty-nine years, and women who keep wine-rooms but forty-seven.

Correspondence.

FEVER AND QUININE.

To the Editor of the Medical Record.

Sir: In the Medical Record for July 18, 1891, Dr. W. A. Plecker, of Glasgow, Va., does me the honor to differ with me in diagnosis under the title of "An Unnamed Fever of the South," but he does not seem to have done me the prior honor of carefully reading my article. Except in three or four instances, the histories of his cases were not comparable to those of mine.

Returning the favor of Dr. Plecker, I would respectfully submit that his fever was probably rightly christened malaria, by the one-half of the Birmingham, Ala., Medical Society. The authors do not speak of a continued malarial fever, and there may be no such disease, but this remains to be demonstrated by Southern country authors, not by men who live in cities, especially not by authors living in New York and Philadelphia, the hitherto *fons et origo* of medical publications. As has been well said, the chapter on fever needs rewriting, and I would add, that a portion of the chapter on quinine also needs rewriting, especially as to how and when to give quinine. In my judgement the best authority on the therapeusis of quinine was the late Professor O. F. Manson, of Richmond, Va., but for thirty years a country practitioner in North Carolina. I think that he taught that the best time in which to give quinine was after twelve o'clock midnight, when it would act with more certainty, and a less dose would be required. He did not use sedative doses of quinine, twenty grains, and probably did not resort to it in diagnosis. Neither, of course, did he claim that quinine would invariably cure malaria—nor if fever, a symptom, was affected by its use, that the disease was necessarily of malarial origin, and *vice versa*.

The disease which I reported some time since is not confined to the country, but has of late years puzzled the doctors in nomenclature in Buffalo, N. Y., and if we know with certainty that it takes twenty-four hours of a continuous warm temperature to generate malaria, then there was no malarial element in my cases.

ANOTHER SIDE TO THE "MATERNAL IMPRESSIONS" QUESTION.

To the Editor of the Medical Record.

Sir: In the Medical Record of July 11th is an article relating to the "Influence of Maternal Impressions upon the Fœtus." The article is very interesting, and much less vague than most articles of its class. However, as I happen to be in partial sympathy with the "coincidence man," I wish to help him a little, but without any animosity toward the "maternal impression" devotee.

According to the views expressed in this article, an impression, in order to so act upon the fœtus as to produce any unusual effect, must occupy the mind of the mother for quite a length of time. She seems to brood over it as a trouble, and occupies her mind with it for a considerable length of time. Otherwise, every fright or bad impression might work harm by stamping the fœtus with all manner of monstrous features. Supposing this to be true, how is it that maternal impressions can be carried into effect in the lower animals? In the spring of 1890, I saw, within one month's time, three pigs that showed either an arrest of development or influence of maternal impressions. One pig had no anal orifice, the fæces being evacuated through the vulva. Another had but one hind limb, with absolutely no sign of any thigh or leg on the opposite side. The third had no ears and no aural apertures. These pigs were owned on three separate farms. None of them had a common parentage. There were no pigs of this description in the vicinity previous to these being dropped. The sows in their slumbers must have had visions of strangely imperfect pigs, thus causing their offspring to be born with such glaring imperfections. I can account for the "impressions" in no other way.

In March, 1888, I saw a colt with a partial hare-lip. The mare had, previous to the time of foaling, been worked by a man having a hare-lip. Perhaps that explained the hare-lip on the colt.

If "maternal impressions" are so potent, can we not attribute change of species to "influence of maternal impressions," thus giving the disciples of Darwin a clue to the missing link? E. H. Smith, M. D.

THE PATHOLOGY OF THE ECLAMPSIA AND ALBUMINURIA OF PREGNANCY.[1]

BY R. VAN SANTVOORD, M.D.,

NEW YORK.

A VERY exceptional opportunity for following a case of albuminuria, with eclamptic and other nervous symptoms, through two successive pregnancies, enabled me to make certain observations of interest in regard to the correlation existing between the renal and nervous phenomena. It has seemed to me that a summary of the present views held in regard to the subject, and a study of this case in the light of the opinions of others and of certain less complete observations of my own, might profitably engage the attention of the Academy.

It is generally recognized that albuminuria in pregnant women may be due to any of the various causes which give rise to it in non-pregnant individuals. Pregnant women may have chronic Bright's disease, acute Bright's disease of infectious origin, cardiac lesions, etc. Yet there can be no doubt that pregnancy itself in some way is a cause of a large number of albuminurias and attendant nervous phenomena. In individual cases, however, especially when nothing is known of the previous history of the patient, it is often difficult or impossible to determine whether or not an existing albuminuria is dependent upon the pregnancy, upon pre-existing disease, or intercurrent complication. In the case about to be cited, my professional acquaintance with the patient for years before pregnancy, the development of albuminuria under observation during two successive pregnancies, and its disappearance shortly after delivery, with return of the patient to good general health, prove conclusively that it was a typical case of albuminuria due to pregnancy.

The fact that albuminuria and its associated phenomena are most often met with in primiparæ and twin pregnancies, gave rise to the supposition that they were due in some way to mechanical causes. The lesion found post mortem in the kidneys, in the majority of cases in which any marked lesion was present, has been parenchymatous degeneration with no involvement of the interstitial tissue. Where other changes have been found, it has been argued with much plausibility that they are due to something besides pregnancy (Bartels). Experimentally, it has been shown that such a lesion may be caused by marked temporary obstruction of the renal veins, complete or partial temporary obstruction of the renal arteries, and by tying the ureters. Direct pressure on the renal veins by the pregnant uterus was the earliest proposed explanation. Bartels, however, has shown this to be anatomically impossible, and Cohnheim calls attention to the fact that usually the kidneys in this affection are markedly anæmic, and show no evidence of venous congestion. To these objections it is answered that the general increase in abdominal pressure may be sufficient without direct pressure of the uterus on the veins, and that, as autopsies are usually obtained only after the uterus has been emptied of its contents, the venous congestion may have disappeared (Rosenstein). Albuminuria has, however, been observed to develop during the early months of pregnancy, and not infrequently disappears before delivery. This theory, therefore, seems to be as lacking in probability as it is in anatomical proof of its correctness. The same, I think, may be said of the supposition that the increased abdominal pressure may be sufficient to cause anæmia of the kidney by direct compression of the organ (Senator). A third theory, viz., that of temporary anæmia caused by arterial spasm, will be discussed later.

Halbertsma [2] is convinced that more or less complete suppression of the urine, due to compression of the ureters at the pelvic brim, especially during labor, by the pregnant uterus, causes albuminuria and eclampsia, and he appeals to Söhlein's [3] observations in 32 autopsies of women dying after puerperal eclampsia. In 8 of these cases, dilatation of one or both ureters was found above the pelvic brim, no cause for which was obvious at time of autopsy (made after delivery), and all of which seemed referable to uterine compression. In 123 non-eclamptic women dying before, during, or after labor, in 4 only was there any dilatation of the ureters, and in 3 of these there was sufficient cause found either in old processes or recent pelvic exudation. Cohnheim objects to this theory, that in the great majority of cases no dilatation of the ureters and no œdema of the kidneys is found post mortem. Söhlein himself says that in all of his 8 cases some pathological changes in addition to those of the ureters were found, especially in the urinary organs, such as are frequently the only pathological changes in patients dying of eclampsia. He concludes that when an already insufficient excretion of urine from the kidneys exists, a new hinderance or interruption of the secretion of urine, due to the compression of the ureters, may give rise to uræmic symptoms or prolong those already in existence. This conclusion seems reasonable. A case recorded by Fleischlein [4] in which, while both kidneys were fatty, that on the side of a dilated ureter was most affected, is in accordance with this idea, that compression of the ureters may be a factor in the causation of the lesion under discussion in some cases, but exceptional and of minor importance.

Still another possible mechanical cause of renal congestion and albuminuria is spoken of by Senator,[4] viz., the interference with the pulmonary circulation by the pressing upward of the diaphragm. That this factor may have some effect cannot be denied, but that this is the main cause of a malady which differs widely in its clinical course and post-mortem lesions from what is known to follow obstructed circulation through the thoracic viscera in other connections, is not claimed by him.

The great interest attached to the study of this form of albuminuria lies in its intimate association with eclampsia. For some writers, Carl Braun,[5] for instance, eclampsia, occurring during pregnancy, labor, or after labor, is simply uræmia, dependent upon renal insufficiency due to acute parenchymatous nephritis. The unsatisfactory nature of the attempts to explain this nephritis on purely mechanical grounds has been commented upon above. Certain other objections to their acceptance will be offered in the discussion of the relation between the disturbance of the renal function and eclampsia.

A great objection to the uræmic theory of puerperal

[1] Read before the New York Academy of Medicine, June 4, 1891.

eclampsia has been found in the fact that a very considerable number of cases have been recorded in which no albuminaria has been present before the occurrence of convulsions, and no grave renal lesions have been found post mortem. These are too numerous, and vouched for by too good authority, to be ascribed to imperfect observation. This unquestionable fact has led many writers, among them Nothnagel, to divide the cases into two categories, the uræmic and the non-uræmic, acute epileptic or eclamptic proper. the latter being supposed to be caused by reflex influences. An essential unity has however been insisted upon by many writers, one group regarding all the cases as of uræmic or toxæmic origin, the other regarding all as reflex. Among the latter, Osthoff [1] may be selected as the sturdiest supporter of the theory. He concludes that the essential cause of all forms of renal lesions and eclampsia occurring during pregnancy, labor, or after labor, is an unusually strong innervation of the splanchnics which results from the movements of the uterus in all stages of its growth and involution, and which extends itself to the vaso-constrictors of the kidneys, causing anæmia and degeneration, or to the vasomotors of the medulla, causing convulsions, sometimes without previous affections of the kidneys. Convulsions occurring in other forms of nephritis he regards as reflex from the kidneys.

In support of this view he cites a case of his own in which, shortly after a first pregnancy, œdema, convulsions, albuminuria, and abortion were said to have occurred. Osthoff watched her through two succeeding later pregnancies, during which she had numerous and violent epileptiform convulsions, but during which the urine was never deficient in quantity, never contained casts, and never albumin, except shortly after delivery. She had obscure vision and high-tension pulse.

The fact that eclampsia occurs with greatest frequency during labor, when reflex excitation is greatest, and that albuminuria occurring, according to various observers, in a percentage of only five downward in pregnant women, is observed in percentages of from seventeen upward immediately after delivery, speaks very strongly, he thinks, for this theory. In support of the same, Santos [2] suggests, in addition to the above, the predominant frequency of eclampsia in primiparæ, twin pregnancies, and in women at full term in whom the uterine nerves are probably most compressed, labors artificially ended, young subjects in whom reflexes are more active than in older persons, and the quick disappearance of the albuminuria after the uterus is emptied. The reason why these reflex influences produce such effects only in a limited number of individuals is to be sought, he thinks, in the neurotic character of those who are affected.

Osthoff, in addition to the above considerations, points to the fact that drugs, such as pilocarpine and the nitrites, which cause arterial relaxation also have a controlling influence over so-called anæmic symptoms, the idea that the elimination of toxic substances through the sweating caused by the first-mentioned drug is of importance, being rejected by him. The controlling effect of chloroform, chloral, and morphia, he thinks, points to the same conclusion.

There are certain details of this theory which are worthy of consideration. According to Traube, convulsions during pregnancy, and in Bright's disease generally, are caused by anæmia of the brain due to cerebral œdema, which is brought about by hydræmia and high arterial tension, not being directly due to the kidney disease at all. This explanation is adhered to by Rosenstein. Although on post-mortem examination in cases of eclampsia, the brain has been found anæmic and œdematous more often than in any other condition, yet it has been also found congested, etc., as Cohnheim insists, without any obvious pathological change.[3] It seems, therefore, most plausible to regard the œdema or congestion, when present, as due to the convulsions, the variety in the brain conditions found on autopsy depending on the length of time elapsing between the convulsions and death, and the varying conditions of the heart and respiratory organs in different cases. It is, I think, now regarded as probable by most pathologists that, as the reflex theory supposes, the immediate exciting cause of epileptical convulsions is anæmia of the motor centres due to arterial contraction. To a slighter but more general and constant arterial contraction of reflex origin is attributed by Osthoff the high arterial tension of the malady. After labor it not infrequently happens that no urine reaches the bladder for several hours. During eclamptic attacks little or no urine is secreted (Cohnheim). These phenomena seem best explained by supposing a more or less prolonged contraction of the renal arteries to take place. Cohnheim [1] calls attention to the fact that the renal changes found after death from eclampsia are often very slight, or altogether wanting. He attributes the eclamptic seizure to the holding back in the blood of the urinary constituents by cramps of the renal arteries.

After delivery albumin is found temporarily in a large percentage of women. Among 600 cases Santos [2] found albumin in 356, or 59.33 per cent., the urine being drawn by catheter, and tested by boiling and Heller's test. The percentage found by other observers is much less (see Osthoff), but the fact seems to be well established. It may be plausibly argued that this albuminuria results from deranged nutrition of the kidney due to vascular cramps. It may be likened to the phenomena of dead and cyanotic fingers in Raynaud's disease, the less marked of which, viz., the dead fingers, is, according to Dieulafoy, common in Bright's disease. Whatever view may be taken of the etiology of the actual necrosis in this malady, these transitory phenomena seem best explained by arterial contraction. Drs. Coleman and Taylor,[3] during these attacks of cyanosis in a case of Raynaud's disease, found coloration and breaking down of blood-corpuscles, and coloration of the liquor sanguinis in blood drawn from the affected fingers. This looks like demonstration that vascular cramps may be sufficient to cause grave changes in nutrition, and supports the assumption that vascular cramps may be sufficient to produce alterations in the renal tissue such as have been produced by experimental temporary lessening or shutting off of the blood-supply from those organs.

If, then, we grant that arterial contraction is probably the immediate cause of the cerebral anæmia inducing eclampsia, and that it is also the cause of the aneuria during convulsions and labor, and sometimes of disturbance of renal nutrition sufficient to allow albumin to pass through the glomerular vessels in recognizable quantities; granting also that reflex or emotional causes may in exceptional cases, in the pregnant as in the non-pregnant adult (Nothnagel) cause epileptoid convulsions; do all the known facts warrant us in accepting this theory of reflex origin as applicable to the great majority of cases?

To this I must answer no, and it is because the case about to be cited strongly supports another view of the subject, that I have ventured to bring it before you. There is a group of writers who still adhere to the old view, that puerperal eclampsia is essentially toxic in its origin. While the renal incompetence due to a parenchymatous nephritis is of course a matter of great importance, the essential element of the disease is to be regarded as a toxæmia which itself is the cause of the nephritis, and which may become so intense that even normal kidneys may not be able to eliminate the poison with rapidity enough to prevent grave results.

In 1847 Virchow pointed out that changes were found, both in the liver and the spleen, in women who died of

puerperal eclampsia. and expressed the opinion that attention had been devoted too exclusively to the kidneys in the study of this affection.[1] This suggestion has been greatly elaborated by Rivière, the experiments of Bouchard forming the basis of his theory.[2] Bouchard has discovered two convulsion-producing ingredients in the normal urine, one an organic substance which he has not been able to completely isolate, the other potassium and its salts. The proportion of thè convulsants present in the urine of the same individual differs very much according to his varying states of health. Toxic matters are introduced into the body with the food. They are produced in the body by intestinal decomposition, by the organs of secretion (the bile especially being very toxic if not properly disposed of), by the processes of disassimilation. The system is protected from the poisons absorbed from the intestinal tract by the liver, which has experimentally been proved capable of destroying toxic alkaloids, and by the fecal evacuations. In the pregnant woman, disturbances of digestion tend to increase the amount of toxic matter capable of absorption, while the constipation commonly present, the interference with the respiratory apparatus, and the unfavorable conditions in which the kidneys are called upon to do an unusual amount of work, all tend to interfere with prompt elimination. But above all, the fatty degeneration of the liver prevents it from perfectly fulfilling its function of converting noxious matters into less harmful forms. Hence it may happen that the patient may be overwhelmed by an excess of poison before the kidneys have been appreciably irritated. This, in brief, is Rivière's auto-intoxication theory, and it is one that is held in one form or another by probably the majority of writers.

The hepatic lesions, which act a prominent part according to this theory, have recently been studied with care by Pillier[3] in eleven cases. He states that these livers varied from a bright yellow to a gutta-percha color. The liver cells were sometimes fatty, sometimes the seat of necrotic changes similar to those found in infectious diseases. The more or less numerous spots commonly seen and regarded as ecchymoses, he found to consist, in the earliest stage, of dilatation of interlobular capillaries. Later a necrotic focus appears in the centre, and later still this necrotic portion is separated as a sequestrum by round-cell infiltration at its periphery. The theories of causation of the hepatic lesions are, 1st, the microbic; 2d, that they are due to poison generated by the patients themselves (Rivière), or to chloroform; this latter supposition being disproved by the fact that they have been found when chloroform has not been used; and 3d, mechanical—due to injury to the liver during labor. One author only, as far as I know, has found a microbe to explain the disease.[4] As his investigations were based only on examination of the urine, they must be regarded as entirely inconclusive, as the presence of a microbe in the bladder of a woman does not prove that it exists anywhere else in her body.

Another recent contribution of interest and probable importance in connection with these hepatic lesions is that of Virchow.[5] In five cases of puerperal eclampsia he found more or less extensive fatty embolism in the lungs and in the renal vessels—chiefly confined in the latter to the glomeruli. Most of these cases died with marked obstruction of the pulmonary circulation. No cerebral emboli were found. The kidneys were not much changed, the cortex being anæmic, the pyramids relatively red, the epithelium of the convoluted tubes cloudy. With these changes, the ones ordinarily found in eclampsia, he did not think the fatty embolism had anything to do. The source of the embolism he did not know. It might be the pelvic fat, in all the cases some laceration of the vagina or vaginal outlet existing. It might be the liver, fat being forced into the hepatic veins by the traumatism inflicted on that organ during convulsions and labor. The embolism did not have any causal connection with the eclampsia, but in a weak person he thought slight fatty embolism of the lungs might be enough to cause pulmonary œdema and death.

In a case seen by the writer, while in coma from which she never recovered, following a single convulsion, the thought occurred to him that the patient's condition might in part be due to the falling back of the tongue into the pharynx, and on subsequent reflection he regretted not having made a more persistent effort to relieve this possible source of danger. Virchow's observation, and this possibility, are instances of factors affecting the respiratory apparatus which might well explain differences in the condition of the brain after death.

In closing this portion of my paper I cannot refrain from briefly calling attention to the analogy which exists between the malady which we are discussing and some forms of chronic renal disease. It has occurred probably to most of us to see cases in which vascular disease or general disturbance of nutrition has been very much out of proportion to any demonstrable insufficiency of the kidneys, but in which the renal lesions and other symptoms seem to be due to a common cause. Senator says that the renal lesions in Bright's disease "have, as is now generally recognized, their origin frequently, if not always, in an abnormal condition of the blood in the most general sense, *i.e.*, in an acute or chronic dyscrasia due to faulty mixing of the normal constituents, or to the addition of foreign and toxic substances."[1]

Renal diseases associated with infectious processes are due directly or indirectly to the action of infecting organisms. In other cases the morbid blood state seems due to some disturbance of the organic functions of the body itself. There seems to be a fundamental fault of assimilation or metabolism back of the whole symptom-complex, differing, perhaps, in different cases, the exact nature of which is almost wholly unknown notwithstanding the numerous hypotheses concerning it. The process back of many cases of cirrhotic kidney we call gout, and know something about. That some similar process is back of other forms of kidney lesion involving primarily the renal parenchyma, seems probable. It may be that the faulty metabolism in these cases differs from that in the malady we are considering only in being less intense in its action, and depending on more permanent exciting causes. Some years ago I attended, toward the end of her life, a lady suffering from chronic nephritis with cardiac complications, whose kidneys were first known to be disordered twenty-five years before, during pregnancy. It seems plausible to assume that this individual had a tendency to some form of the faulty metabolism which probably lies back of renal disease, which is not due to irritants introduced from without, which was called into activity at one time by pregnancy, later by other exciting cause or causes. This may, in general, be the explanation of the not very rare cases in which chronic nephritis is said to have followed renal trouble first occurring in pregnancy.

Having thus passed in review the known facts and theories relating to the morbid conditions under discussion, I will now give a history of the case, the observation of which led me to present the subject for discussion.

The patient in question had been under my professional care, for occasional slight ailments, for some years before marriage. She suffered from slight irritability of the bladder for years, for which I was not able to find any cause. Her general health had been excellent. Her first pregnancy extended from August 1887, till May 23, 1888. Albumin was first found in her urine March 17th, nine weeks and a half before delivery; the quantity varied very much, fifty-seven per cent. of deposit being the largest amount; it disappearing entirely for a week in the early part of April. On six occasions the quantity

[1] Die Albuminurie, etc., p. 108.

of urea passed in twenty-four hours was estimated as follows:

March 18th.—700 c.c.; specific gravity, 1.026; alk.; albumin about sixteen per cent.; urea, 20.3 grammes. Patient was taking four-drop doses of a two per cent. solution of nitro-glycerine, which caused some headache. Suffered from slight nausea and constipation.

March 20th.—420 c.c. (some lost with stool); specific gravity, 1.030; acid; albumin, eighteen per cent.; urea, 9.66 grammes + (what was lost with stool). Patient taking gtt. ij. of nitro-glycerine solution every three hours, and tincture of strophanthus, gtt. x. t.i.d. Feeling subjectively cool.

March 22d.—580 c.c. (some lost with stool); specific gravity, 1 016; acid; albumin. 57; urea, 11.89 grammes + (what was lost with stool). Patient comfortable. Taking strophanthus and nitro-glycerine as above, the latter increased to 3 gtt. doses.

March 23d.—Urine, about one pint; acid; albumin, 32; urea, about 12 grammes.

March 30th.—Urine, one and a half pint; specific gravity, 1.017½; acid, clear with Tanret's test; showed a few flocculi on standing after being boiled and treated with nitric acid; urea, 13.48 grammes. Patient had been sitting up for three days, feeling well. Stopped nitro-glycerine and strophanthus. Gave citrate of potash, gr. xv. t.i.d.

Throughout the next month the patient was comfortable, the nitro-glycerine and strophanthus being resumed, alternating with the citrate of potash. Three weeks before delivery she suffered from much backache, with pains shooting into left groin. This was lessened by the citrate of potash, and very greatly helped by salol, gr. x. t.i.d., given through a druggist's error in place of betol. The urine became black very soon under its influence, but no marked effect on the albuminuria was produced. It was noted that the urine was much less turbid than it had been before its use.

On the morning before delivery, one and one-quarter quart of urine was recorded as having been passed in twenty-four hours, containing no albumin. The delivery was uneventful, a healthy boy being born. No urine was secreted for twelve hours after delivery, as determined by the catheter. Five weeks after delivery the urine was found to be free from albumin; specific gravity, 1.018. Repeated examinations failed to show any casts in the urine, which was always turbid and showed rather more pus than the customary vaginal discharge would account for. Spots before eyes, œdema of feet and legs, slight headache, and general malaise were the symptoms most complained of. Sphygmographic tracings showed a very high tension pulse, except on one occasion, when she had felt faint after a dose of nitro-glycerine. The tracing was taken two hours after the dose, a period of time in which usually all effect of the drug, on other occasions, was found to have disappeared.

After a period of twenty one months, during which her health had been good, patient again became pregnant, in February, 1890. Nothing abnormal occurred except a slight attack of sciatica, until August 16th, about the end of the sixth month of pregnancy, when she lost consciousness suddenly for a short time without apparent cause, being at the time away from the city. Soon after she began to suffer from headache, spots before the eyes, and some pains shooting from the loin downward and forward, as in previous pregnancy. The urine on July 21st showed a specific gravity of 1.010; acid; no albumin. When examined after her return to the city, on September 2d, albumin was found; milk diet, confinement to bed, and hot baths were given.

September 4th.—Given nitro-glycerine (two per cent. solution), gtt. ij., every three hours. Milk not being well borne, diet changed to cereals, fruit, and vegetables, with small allowance of meat once daily.

September 6th.—Feeling comfortable. Allowed to get up. Nitro-glycerine continued.

Urine for last twenty-four hours, 790 c.c. (26.7 ounces); specific gravity, 1.020; acid; faint trace of albumin; urea, 12.64 grammes. For two weeks the patient remained feeling well. On the 17th the urinary examination showed 44 ounces for twenty-four hours; specific gravity, 1.013; acid; albumin trace on boiling, adding nitric acid, and allowing it to stand for several hours. On the morning of the 20th the urine was recorded as showing 36 ounces secreted in twenty-four hours; specific gravity, 1.016; acid; no albumin. She awoke not feeling well, having been tired by a ride on the previous day, but without any local symptoms. She remained in her room all day until evening, then going down to dinner. While at the table, a few moments after a dose of nitro-glycerine, she felt faint, lost consciousness, and had a clonic spasm during which she bit her tongue. The next day she was feeling some malaise and muscular soreness. The urine, examined sixteen hours after the attack, showed a specific gravity of 1.012. No albumin by Heller's test, and only a faint opacity on standing after being boiled and acidulated with nitric acid. She was kept in bed and tincture of digitalis added to the nitro-glycerine, which was still continued. The following day (the 22d) the urine contained sixteen per cent. of albumin. She had shooting pains in the left groin, aching in small of back on left side, nausea during pain. No headache. Slight veil before eyes. Feet not swollen since treatment commenced. To-day mentions that she had suffered from a peculiar nervous feeling behind her knees and a tendency to twitch for some months. Salol, gr. x. t.i.d., added to the nitro-glycerine and digitalis.

September 24th.—Salol reduced to gr. v. t.i.d., on account of carboluria. In afternoon suffered from sharp twinges in the bladder, for which spiritus ætheris nitrosi was given with atropia, gr. $\frac{1}{150}$, in addition to the above, under which the vesical symptoms subsided.

For three successive days at this period the urea passed was estimated as follows: Urine of 24th to 25th, 27 ounces (798.5 c.c.); specific gravity, 1.016; acid; albumin, .03; urea, 8.778 grammes. 25th to 26th, 42 ounces (1,272 c.c.); specific gravity, 1.008; acid; albumin, .075; urea, 8.694. 26th to 27th, 25 ounces + (some lost with stool); specific gravity, 1.020; acid; albumin, .10; urea, 11.18.

On the 27th patient very comfortable. Salol was stopped and nitro-glycerine solution, gtt. ij. every three hours, tincture of digitalis, gtt. x., and spiritus ætheris nitrosi, ℥ j. t.i.d., continued. Urine of September 28th to 29th showed 40 ounces (1,183 c.c.) quantity; specific gravity, 1.015; albumin, .02; urea, 13.57 grammes.

October 5th to 6th.—Urine, 58 ounces (1,715 c.c.); specific gravity, 1.012; acid; no albumin; urea, 15.437 grammes. The albumin had disappeared on the 2d, Heller's test being relied on, and did not reappear until the 18th, the urine varying in the meantime from 42 to 66 ounces under the influence of the nitro-glycerine, digitalis, and sweet spirits of nitre. The patient during this time was sitting up and comfortable, complaining, however, of sight so dim that she could not see to read with comfort, and nervous feelings in her legs.

October 18th.—Ophthalmoscopic examination negative. Tired feeling in back and pain in left groin. Urine, 18th to 19th, 42 ounces (1,242 c.c.); specific gravity, 1.013; acid; albumin, 3.726 grammes (Esbarle's method); urea, 13.63 grammes. Patient noticed that when nitro-glycerine was given, even in a dose of one drop of the two per cent. solution, at the same time with the spirits of nitre and digitalis, disagreeable throbbing sensations were felt all over the body lasting half an hour, no such prolonged effect following two drops of the nitro-glycerine solution when given alone. On this account only half a drop was given when its administration happened to coincide with that of the other drug. Increase of the spiritus ætheris nitrosi to one drachm every three hours, and a short confinement to bed, was followed by disappearance of pain and albumin, none of the latter being

present from October 21st to November 1st, the urine varying in quantity from 24 ounces (one day only) to 44 ounces, the specific gravity remaining somewhat low for the quantity passed.

November 1st.—Had passed 40 ounces (1,330.77 c.c.) of acid urine, containing albumin ½ gramme to the 1,000, and 14.185 grammes of urea. October 30th to 31st, only 24 ounces of urine had been passed, apparently because a new specimen of nitre was not as strong as one previously used. Face and hands were slightly puffy, and feet were swollen. Spirits of nitre, 1½ drachm t.i.d., digitalis and nitro-glycerine as before. From this date to her delivery, on November 15th, the urine fluctuated from 36 to 48 ounces, sometimes free from albumin, according to Heller's test, sometimes containing a little.

On November 24th 45 ounces (1,330.17 c.c.) were passed; specific gravity, .014½; acid; albumin, none by Heller's test—two per cent. on standing when tested by heat and nitric acid; urea, 13.97 grammes.

A healthy nine and three-fourths pound boy was born; painful cramps in the right thigh, rendering chloroform necessary toward the last, being the only complication. Presentation L. O. Q. No urine was passed for eighteen hours after delivery; an attempt made with the catheter by the nurse after twelve hours showed the bladder to be empty. All drugs were stopped except spirits of nitre. Three days after delivery, when large quantities of urine were being passed, 3.2 grammes of albumin per 1,000 were found. Its absence was not again noted until eleven days after delivery, and the quantities being much more than accidental contamination by the lochia would account for (.5 to 4.3 grammes per 1,000).

December 5th.—Urine fell off in quantity after an attack of indigestion, and albumin, 3 grammes per 1,000, was found. None was ever found again after the 13th. The confinement was followed by a prolonged subacute cystitis, which had probably antedated it. Repeated microscopic examinations, made before and after delivery, showed pus more than could be accounted for by vaginal discharge, and often a little blood, which may have come from hæmorrhoids, but no casts. The urine was always turbid when it reached me. On reviewing the case I was led to conclude that the cystitis had existed in a mild form during, and probably before, pregnancy, being of a variety which, I believe, is caused by slight vesical atony and spontaneous bacterial infection of the bladder.[1] Inasmuch as the urine did not contain albumin after delivery, at times when the patient was suffering considerably from her bladder, and as much pus as had ever been noted in it was present, the complicating cystitis was probably responsible only for the vesical pain suffered by the patient and some of the pus found in the urine. The pain in the loin and groin suggested a possible pyelitis, but such pains have been noticed in other cases of the renal disease of pregnancy.

On December 14th to 15th, one month after delivery, the urine was found to be as follows: Quantity, 1,300 c.c. (43.95 ounces); specific gravity, 1.018; albumin, none (Heller); urea, 24.7 grammes; no diuretic being taken.

March 26th to 27th.—Urine, 1,125 c.c. (38 ounces) +, some lost estimated at 10 ounces; specific gravity, 1.021½; alkaline; urea, 19.125 grammes +, that of the quantity lost.

April 14 to 15, 1891.—Quantity, 1,355 c.c. (48.04 ounces); specific gravity, 1.014½; strongly alkaline; no albumin; urea, 18.2925 grammes. In this latter specimen some of the urea had probably been lost by decomposition before examination. The patient's vision cleared up steadily after confinement, and she is now in fair health except from some residual vesical trouble.

On looking for the cause of the disease in this case, I think it evident that the only purely mechanical factor, which, in the above review, was found to have any foundation on observed facts, viz, compression of the ureters, can be excluded because the kidneys throughout reacted readily to diuretics, the absence of mechanical obstruction to the discharge of urine being thus proven, and because the constitutional symptoms of the case were most marked long before labor, which is the time when this factor, if present, is apt to be most prominent. For a similar reason the reflex theory is inapplicable. The one undoubted eclamptic seizure which the patient had occurred almost two months before labor, with no obvious reflex cause. This was all the more striking because the patient suffered from sciatica during pregnancy, and during her second pregnancy suffered extremely from pressure upon the sacral plexus. Wernicke[1] called attention to a group of cases in which he regarded eclampsia as being due to the establishment of an epileptogenous zone, caused by pressure upon the sacral plexus. Here we had such pressure-symptoms, but no coincidence between pressure-symptoms and eclampsia and other nervous phenomena.

We are forced, finally, to consider the applicability of some form of the toxæmic theory in explanation of the case, and the question arises, Were the various nervous symptoms noted due to a primary nephritis, with secondary toxæmia due to insufficiency of the kidneys? The freedom of the patient before, after, and during the earlier portion of both pregnancies from any symptoms, or indications, from the examination of the urine, of chronic kidney disease, the facts that casts were never present, that the amount of albumin when present was usually small, and that the kidneys always readily reacted to a comparatively feeble diuretic, all go to show that the renal involvement was never very extensive. It is, however, to the condition of affairs immediately preceding and following the one undoubted eclamptic seizure that I especially call attention. During the ten days prior to this seizure the urine had been examined four times, its quantity varying from 34 to 44 ounces. On two of these occasions a faint cloudiness was noted on standing after boiling and acidulating with nitric acid; on all Heller's test gave only a negative result. The urine measured for twenty-four hours, up to a time within ten hours of the seizure, showed 36 ounces, a specific gravity of 1.016, acid, and contained no albumin. Here was no evidence whatever of renal disease or renal insufficiency, yet a distinct convulsion occurs without obvious external exciting cause, and preceded only by a feeling of malaise, attributed to having been over-tired on the day previous. The urine passed about sixteen hours after the attack was found to be slightly opaque on standing, after being boiled and acidulated with nitric acid; Heller's test was negative. The second day after the attack the urine contained a deposit of sixteen per cent. of albumin; on the third day, twenty-four per cent.; the albumin again disappearing temporarily on the twelfth day following the convulsion.

Throughout the last three months of this pregnancy, even when the patient was passing large amounts of urine of fair specific gravity, amounting on some days to over sixty ounces, and often free from albumin, the obscureness of vision never left her, and ill-defined nervous symptoms developed whenever the stenosis lessened from any cause. The whole impression of the case was that of a toxæmia, back and wholly independent of renal lesion or insufficiency. Before discussing the nature of this toxæmia, I wish to call attention to details of the albuminuria following the convulsion. Convulsions themselves, have, by not a few writers, been regarded as the cause of albuminuria following them, and even of actual nephritis. If we turn now to Huppert's[2] observations in regard to albuminuria after epilepsy, we find that it was most marked in the urine secreted during the attack, *i.e.*, not necessarily in the urine passed immediately after a convulsion, as that may have been previously secreted. The amount in the great majority of cases was so small that it could be recognized only as a slight opacity after boil-

ing and acidulating with nitric acid and allowing the urine to stand for some hours. The failure of other observers to find albuminuria after convulsions he attributed to their not employing sufficiently delicate tests. Larger amounts of albumin, and even hyaline casts, rarely with blood or epithelium on them, were found after groups of fits in epileptics frequently affected. The casts were usually found only in urine passed about three-quarters of an hour after an attack.

Now in the case under discussion albuminuria followed the convulsion, but the first urine examined after its occurrence, containing only a trace on standing, was passed sixteen hours after the convulsion, larger quantities being found later. Had there been no knowledge of a preceding albuminuria, the fact of a gradual increase in that symptom for several days would have been enough to have negatived the idea of the convulsion as a cause of the albuminuria, the albuminuria due to convulsions being, as above stated, greatest immediately after the fit and disappearing in a few hours. That convulsions can give rise to actual nephritis is a wholly unproved assertion.

To return to the question of the nature of the autotoxæmia in this case, I wish now to point out the bearing of the excretion of urea on the point at issue. On every occasion but one the amount was much below normal. Urea may fail to appear in the urine in normal amount, either because it is not formed in normal quantity or because the kidneys are insufficient. During the first pregnancy six estimates of the quantity passed in twenty-four hours were made, the hypobromite of soda test with the apparatus devised by Dr. C. A. Doremus being used. On one occasion 20.3 grammes were found, a quantity possibly not abnormal. The other five varied from 9.66 grammes +, a little lost with stool, to 13.48 grammes. On all these occasions the urine was considerably below normal in quantity and contained varying percentages of albumin. It might well be questioned, therefore, whether or not the failure to excrete a normal amount of urea may not in this sense have been due to renal insufficiency. The same may be said of other similar cases that I have found reported by Bartels [1] and Herman.[2] In the second pregnancy it was otherwise; nine observations were made, the urea excreted varying from 8.69 grammes to 15.43 grammes. In six of these the quantity of urine was forty ounces or over. In one there was no albumin in the urine; an occasion on which 58 ounces were passed in twenty-four hours, containing 15.43 grammes of urea; in none was it large. The smallest amount of urea excreted in this group was 8.69 grammes. The inference may, I think, be fairly drawn that the amount or urine being normal or above normal, and there being, as above stated, no proof of serious lesion of the kidneys, the excretion of urea was abnormally small, because only an abnormally small quantity was found in the body.

This inference cannot of course be considered as proven in the absence of analysis of the blood. The observation of Semmola,[3] however, that in chronic Bright's disease less urea is found than normally, *i.e.*, that not only is less urea eliminated by the kidneys, but in patients not in an uræmic condition less is found in the blood, adds plausibility to my interpretation of the facts above given.

In my case the lesion present was almost certainly a minor grade of the parenchymatous degeneration characteristic of the renal disease of pregnancy. The comparatively trifling amount and frequent absence of albumin present in the urine was, therefore, more indicative of a correspondingly slight renal lesion than would have been the case had it been a question of a chronic process largely interstitial. Parenchymatous nephritis pretty certainly does not occur without albuminuria. A possible weak point of the case is that the specific gravity of the urine remained slightly below what it normally should have been for the quantity passed, but that the failure of urea, one of the most soluble urinary constituents, to pass through substantially normal kidneys, was the cause of this does not seem probable. On looking for the cause of this probable diminished formation of urea, allowance must of course be made for the restriction as to albuminous food, meat being allowed only at one meal. As the patient ate fairly well throughout her sickness, this limitation was pretty certainly not the cause of a diminution in quantity of urea varying from a little over one-quarter to about two-thirds of what may be assumed to be the normal amount for this person based on the amount passed after recovery.[1] One observer estimates that pregnant women eliminate from 30 to 35 grammes of urea in place of 22 to 24; but Kleinwächter found the amount of urea in one hundred and seventy-nine examinations of lying-in women very nearly normal. The supposition, therefore, seems allowable that the nitrogeneous waste of this patient was not being as completely converted into urea as it should have been, but that it circulated through the body in forms which have been proved by modern research to be decidedly toxic.

In a second case of my own, about ten grammes of urea were found when the patient was passing about one and a half pint of urine containing albumin and casts, mostly hyaline. After the urine had been increased in quantity under acetate of potash, digitalis, and nitro-glycerine, the headache and nervous symptoms passed away. Two examinations of the urine then resulted as follows: Quantity in twenty-four hours, 1,340 c.c.; specific gravity, 1.014; alkaline; albumin, 1.3 gramme per 1,000; urea, 12.06 grammes. Quantity in twenty-four hours, 1,650 c.c.; specific gravity, 1.014½; albumin, 1.2 gramme per 1,000; urea, 14.9 grammes.

This case unfortunately died shortly after a difficult forceps delivery, apparently from internal hemorrhage starting in the left broad ligament. As far as it goes it sustains the views above advocated.

As it has been proven that in grave diseases of the liver the formation of urea is very much lessened, being completely abolished in acute yellow atrophy of that organ,[2] the probability of hepatic insufficiency being the important factor in the disease is evident. As to the causes of the hepatic changes, we may suppose them to be due to excessive work thrown on the organ from its having to act upon the waste of both mother and fœtus—though in this connection the fact that the fœtus also has a liver ought not to be forgotten—to circulatory disturbances, or to those combined with an abnormal vulnerability of the organ; but these are mere suppositions. The fact remains that the liver presents pathological changes. The bearing of the views and observations above given upon practice may be briefly stated as follows:

The periodical examination of the urine for albumin, while important, may fail to give sufficiently early notice of coming danger. The necessity of reporting any of the various nervous symptoms which might be due to toxæmia should be impressed upon some reliable person associated with the patient, as the subjects of this form of disease are apt to be apathetic about their own condition. The estimation of the amount of urea being passed is probably a more valuable index of the real danger of the patient than the presence or estimate of the quantity of albumin in the urine. The necessity of limiting the amount of nitrogeneous food, when an exclusive milk diet is not tolerated, and the possibility of limiting by intestinal antisepsis the amount of poison generated, are the only points of treatment not currently recognized in the text-books which this view of the subject brings forward. It is obvious that elimination can be more successfully effected if the disease is recognized before the kidneys are damaged.

RECTO-ABDOMINAL FISTULA FOLLOWING LAPAROTOMY, TREATED SATISFACTORILY BY IMPROVED DOUBLE-CURRENT IRRIGATION.[1]

By NATHAN G. BOZEMAN, PH.B., M.D.,

NEW YORK,

MEMBER OF THE ALUMNI ASSOCIATION OF THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK; GYNECOLOGIST TO ST. FRANCIS HOSPITAL, JERSEY CITY, N. J., ETC.

In general, extensive sinuses with pus-secreting walls are best drained by perforated soft-rubber tubes, as they are sometimes tortuous, and hard instruments cannot be introduced along their whole extent. Into the perforations the morbid secretions find their way and drain off, and when irrigation is necessary the diseased tissues which impinge against the openings are bathed by appropriate solutions, which when forced in at one end of the tube flow out at the other. But it is not always possible to have a counter-opening, then the drainage and irrigation of sinuses and pus-cavities by the use of soft-rubber tubes becomes an interesting problem. I have obtained very gratifying results with soft-rubber tubes in irrigating and draining the vagina and bladder in cases of urinary fistula,[2] and my treatment in the following interesting case of recto-abdominal fistula illustrates what can be done in long, tortuous sinuses where no counter opening exists.

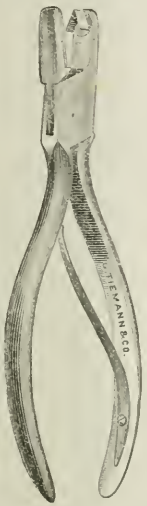

FIG. 1.—Author's 60°-angle Punch.

CASE I.—Mrs. D——, aged forty-seven, married and the mother of one child, was operated on in one of the city hospitals for the removal of both of her ovaries, several months before consulting me. She presented herself at my office in January, 1889, suffering from an abundant and offensive discharge of pus, fecal matter and gas, issuing from an opening large enough to admit the tip of the index finger, in the cicatrix of a median abdominal incision. For a radius of two inches the surrounding skin was red, eroded and very tender. On introducing a probe into the opening, and with the index finger in the vagina, the end of the former could be followed up by the sense of touch through the thick indurated wall of a sinus for five and one-half inches, along the right side of the uterus into the pelvis.

The patient told me that, under the directions of several surgeons, the sinus had been packed daily with strips of iodoform gauze, and that she had worn in the external opening a glass plug with a broad flange, which was held in place by a bandage and pad. Irrigation of the fistulous tract had been tried, but the introduction of the double-current catheter used for the purpose was painful to the patient, and the bowel was kept constantly irritated by the solutions employed, which gravitated into it. Since leaving the hospital she used a Davidson syringe herself, which rendered her condition in this respect still more uncomfortable. To wash out the sinus frequently and free the surrounding skin from contact with the irritating discharges was the form of treatment which the urgency of the case called for. After trying several different double current catheters, I finally improvised a soft-rubber one, which I could make myself. It was provided with small openings along its whole extent, and, being flexible, could be introduced to the bottom of the sinus. Through this I passed very frequently, by means of my continuous irrigator and drain, an intermittent stream of an antiseptic fluid and sterilized air, which, after bathing the walls of the sinus as it issued from the perforations of the tube, was taken up by suction before it had time to gravitate into the rectum or escape from the external orifice. The patient soon learned to introduce the tube herself; she then carried on the douching at her home several times daily, for half an hour at a time. Under this treatment the inflammation in the skin soon disappeared, the induration in the walls of the sinus became very much reduced, and the secretion of pus ceased. During the following four or five months, while I was abroad, the patient used the douche, but less frequently, and, on my return, she showed me a silk ligature which had been washed out. She wore a pad then over the opening, which became only slightly stained during the twenty-four hours.

The soft-rubber double-current drainage tube which I have referred to I made of tubing the size of a No. 6 catheter (E.), which I introduced double. I made a number of openings along one-half of it and passed a wire through it to produce sufficient stiffness for introduction. The exact amount of substance, though, which would cause its calibre to become obliterated when sharply bent on itself I had removed with scissors. Since then Messrs. George Tiemann & Co. have perfected under my directions a punch (Fig. 1) for the purpose, the cutting edge of which incloses an angle of 60°. It makes a smooth notch in a soft-rubber tube by removing a wedge-shaped segment from its side.

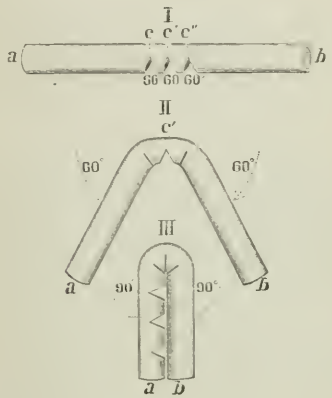

FIG. 2.—Diagram Showing the Process of Bending a Tube without Obstructing its Calibre.

Now to produce a symmetrical bend in any portion of a tube three points are taken along its central axis, the distance between them being equal to the diameter of the tube which is used. The apices of three angles of 60° each are thus located, which are made by successive applications of the punch, and between the triangular spaces produced very small portions or bridges of the tube are left intact, which, when brought together, by bending, form the wall in the re-entrant angle. To be more explicit, when the extremities of the tube are brought into parallelism, *a* (Fig. 2) must sweep through an angle of 60°, the centre of rotation being at *c*, and *b* also moves through one of an equal number of degrees, the centre of rotation being at *c''*. Then by making *c'* the centre of rotation and approximating *a* and *b* still farther it will be readily seen that they each sweep through an additional angle of 30° and become parallel, the calibre of the tube, of course, remaining the same throughout.

In all my cases of ovariotomy, when there is oozing, I introduce this tube inside of the ordinary glass one which I use, and draw up the secretions into a medicine-dropper, without disturbing the dressings. The air which is sucked in is of course sterilized, because it is filtered through the antiseptic coverings of the wound. After forty-eight hours I am accustomed to remove the glass

[2] The After-treatment of Kolpo-Uretero-Cystotomy, etc., New York Medical Journal, June 1, 1889.

drainage-tube by slipping it out, at the same time holding the double-current one in its position.

Dr. Wiley said he had had a great deal of experience with these openings after laparotomies and his experience was, it was not drainage that was at fault, for as long as a foreign body or irritating thread remained at the bottom of the sinus they were certain of trouble. Where these sinuses are of long standing this condition is almost invariably due to the presence of the thread. He had some cases where he made a counter-drainage through the vagina and got through drainage in that way. He had succeeded in curing the patient, even where there was an opening in the intestine, by making a counter-opening through the vagina.

Dr. Bozeman, in closing the discussion, said he agreed with Dr. Wiley in regard to the thread and he thought by keeping the sinus open and having it distended as much as possible he would in that way afford an avenue for the thread to come out. He did not give this method as a radical cure. It was simply a way to make the patient comfortable, but the result in this case was virtually a cure.

PERSONAL IDENTITY DETERMINED BY SCAR AND OTHER BODY-MARKS.[1]

By Colonel CHARLES R. GREENLEAF, M.D.,

AND

Major CHARLES SMART, M.D.,

MEDICAL DEPARTMENT, UNITED STATES ARMY.

Some three years ago desertion from the United States Army became so frequent as to attract public attention. The probable causes were discussed not only in the military journals, but in the daily press. Soldiers were interviewed as to their grievances, and the enterprising American reporter did not hesitate to enlist and go through the routine of the recruiting rendezvous and depot in his endeavor to satisfy the public interest in the matter. Local conditions were assumed by these inexperienced observers to be general, and desertion was attributed to as many causes as there were observers, interviewers, or interviewed grumblers in the ranks. Officers of the army knew how groundless were the charges of military mismanagement in relation to the comfort and well-being of the enlisted men, and referred desertion to the restlessness of the men,

"Ever seeking something new,"

their failure to recognize the binding nature of their contract with the Government, the ease with which desertion was effected, and the inadequacy of the efforts to pursue, arrest, and punish. If the deserter was not captured while making his escape, he was afterward safe, for the only effort made by the Government to recover him was the offer of a reward so small that for it no citizen of the United States would be tempted to throw a man into a military prison by informing, unless a personal grudge or quarrel came in as a controlling factor. So easy was it to desert, and so slight the risk of capture and punishment, that some officers of the army, among whom were the writers of this paper, believed that the reported number of deserters did not represent an equal number of men who had enlisted and deserted, but that one man swelled the record under different names, enlisting if hard pressed for present subsistence, or if desirous of free transportation from one part of the country to another, and going off when his personal object was accomplished.

To suppress this a method of determining the identity of the individual was needful. At this time the anthropometric method of Bertillon was being adopted with enthusiasm by the prison wardens and superintendents of the country. This was, therefore, carefully considered in relation to the object in view. As an index to a large number of individualities it seems excellent, dividing them into smaller numbers with which an individual record may be compared; but trustworthy only if the measurements are accurate. Now, as our records of the measurements of the height of recruits by our medical and recruiting officers showed us that in following the record of an individual we should have to pursue three trails—the recorded height and two others, one a half inch above and the other a half inch below the recorded height—we came to the conclusion that in adopting the Bertillon system we should have, in tracing a single individual, to follow no less than twenty-one to thirty different trails, as there are from seven to ten or more measurements to be made, and each, according to our intimate knowledge of the work of our medical and recruiting officers, would require three branches of investigation if the subject were to be carefully followed up. Moreover, granted that our officers should become as enthusiastic anthropometricians as some of our prison superintendents, and their measurements should be accepted as within the limits of allowable error, their statements of the measurements would give no guarantee of the identity of the individual to the officers of a court-martial. These officers would individually have no difficulty in recognizing identity if the reputed individuals were each of the same height, color of eyes, apparent age, and nationality, and had each a brown mole over the xiphoid cartilage, an oblique scar half an inch long across the back of the interphalangeal joint of the left thumb, the lobe of the left ear chopped off, and the letters X Y Z with certain other specified flourishes tattooed on his right forearm. They would recognize these personal marks and condemn; but it is a question whether they would be scientific enough to condemn on the coincidence of measurements which have allowable limits of error and some of which may, as is well known, be modified by the effort of the subject at deception.

The system of Bertillon takes cognizance of these personal marks and scars as collateral evidence; but to us this collateral evidence appeared to be the primary evidence that would prove or disprove the case; and as we considered that the men whom we desired to detect were not such as would be likely to have lived their lives without incurring scars, we concluded that a careful record of these personal marks would suffice to determine identity without the various measurements of the anthropometric system. The accuracy of our conclusions will be shown directly.

That which was needful was evidently a full and precise record of the permanent marks on the body of every man in the army. We planned an outline figure card on which such marks should be recorded. One side of the card gave a view of the anterior surface of the body, the other gave the posterior surface; both were divided by dotted lines into regions, so that the situation, size, obliquity, etc., of a mark or scar could be seen at a glance independent of any detailed description. In connection with this figure card we elaborated a plan which in theory was as follows: Let our file-boxes contain a card for every enlisted man of the army, showing on it every permanent mark, scar, or peculiarity of the individual at the time of his enlistment. These cards would represent the army, not as organized into corps and regiments, but arranged alphabetically for convenience of reference. Let us have also every change in the personnel of the army promptly reported and noted, so that our file boxes of cards should always represent the army by the addition of the cards of recruits and the withdrawal of those discharged, dead, deserted, etc. In progress of time we should accumulate a lagre number of cards of men who had deserted or been discharged for disability or misconduct; and our object would then be to prevent the enlistment of any man who had a dishonorable record. Each morning's mail would bring us the changes that had taken place in the personnel of the army. So many noti-

[1] Read by Brevet Lieutenant-Colonel A. A. Woodhull, United States Army, at the recent meeting of the International Congress of ygiene and Demography in London, England.

fications of discharge, desertion, etc., and so many cards of newly enlisted men. The work of the office would resolve itself into noting the losses by desertion, etc., and comparing the cards of the recruits with those of deserters and others of bad record to ensure that these men should not again effect an entrance into the army.

Obviously the best method of instituting a system of this kind would have been to have called for the card of every man in the army, of recruits as enlisted, and for the notification of losses day by day as they occurred; but as superior authority did not have confidence in our ability to effect any practical good by this project we did not feel authorized to ask for all that we desired, but determined to do the best we could with the means available.

Accordingly, as a beginning, on April 1, 1889, the outline figure card was called for from every medical and recruiting officer and the following instructions were issued:

"Hereafter a record of such indelible or permanent marks as may be found upon the person of an accepted recruit will be made upon an outline figure card, as illustrated on accompanying pages of this order, and forwarded promptly on completion to the Surgeon-General of the army. No letter of transmittal is required. The outline cards will be furnished by the Adjutant-General.

"The examination and record of marks of recruits belonging to the general service will be made by the medical officer at a depot; of recruits enlisted at military posts, by the post or attending surgeon; and of recruits enlisted at other places where the services of a post or attending surgeon cannot be obtained, by the enlisting officer. In the cases referred to in section 1, the record of marks will be made at the second examination.

"The object of this record is to obtain evidence for the identification of men who have had previous service in the army, and its successful accomplishment depends upon a rigorous precision in noting on the card all personal markings or peculiarities. The following directions should therefore be strictly observed: Make a careful search of the body, front and rear, on each side of the median line, separately commencing at the scalp and ending at the foot, for any scars, moles, tattoo marks, etc., that may exist, indicating their position on the body by a dot made with pen and ink at a corresponding point on the figure card; on its blank fly-leaf note the *general inclination*, whether vertical, oblique, or horizontal; the *form*, rectilineal, curved (inward or outward), oval, circular, undulated, or oblong; the *character*, if scar, whether recent, permanent, or transient; if mole, hairy or otherwise, etc.; and the distance of the mark from some fixed anatomical point, for example: Scar, from burn, 1¾ inch above, and 1 inch to the right of left nipple, oblique, curved inward. When numerous small scars are found on the back, from pimples, or on the fingers, from cuts, note them as 'numerous scars,' or describe the principal one and add the words, 'and many others;' describe briefly tattoo marks and distortions of the finger- and toe-nails, *i.e.*, the striated or split nail of the finger, or the hypertrophied nail of the great toe. If, after careful search, no personal marking is found, the fact should be noted on the figure card."

When some three thousand cards had been collected they were carefully studied with the view of determining the best method of comparing one card with the others for the purpose of detecting identity. The first practical result of this study was to show the carelessness of the examining and recruiting officers, as manifested by the large number of cards which showed no marks whatever on the individual. Communications were sent to those officers calling for an intimation on the card of some characteristic which would distinguish one man at a given height and color of eyes from another; and later, when it was found that certain medical officers paid special attention to the making out of these cards, the card which reported no marks was returned to the officer who rendered the report requesting a special examination in the case and inviting his attention to the fact that the cards received from a certain depot averaged 17 scars, moles, and other permanent marks in addition to vaccinations and tattoos, and suggesting that the report of no marks in the case in question was due to carelessness in examination. After this a manifest improvement was observable in the cards received, which of course increased their value for the purpose in view.

The study of these three thousand cards showed that they could be divided into sections for comparison in accordance with height, color of eyes, and the regions on which the scars were noted. Dividing the men into tall men of over sixty-eight inches, small men of under sixty-six inches, and men of medium height, we had three grand divisions which became split into six according as the iris was brown in color or of some shade of blue or gray. The uncertainty of the record in many instances led us to consolidate the blue and gray eyes. We had thus six primary divisions dependent on height and color of eyes, to be broken up into smaller sections by the body marks and scars. Presuming that a scar on the face would be observed and noted, no matter what marks or scars there might be on other parts of the body, this constituted the first section of the division. The card of a man who had no marks on his face would not be looked for in that section, but if he had a scar on the palmar surface of the hand, of the wrist, of the anterior surface of the forearm or arm, his card would be compared with those of the deserters and others of bad record who had no scar on the face, but who had marks on the hand, wrist, forearm, or arm. Scars or marks on the anterior surface of the body took precedence of those on the posterior surface as an index for dividing the cards into smaller packets for purposes of comparison. Thus the card of a recruit sixty-nine inches in height, with gray eyes, and the only recorded scar the cicatrix of a boil on his buttock, would not be looked for among those of medium or small stature, nor among those of brown eyes, nor among the tall men with blue or gray eyes who had scars or marks on the face or other anterior regions of the body, but only among those having marks on the posterior surface. By a systematic division of this kind our three thousand cards could be divided into sections, the largest containing not more than fifty cards.

But the practical work of comparing the cards speedily developed that this system, however pretty in theory, was by no means so satisfactory as a general study of the card in question and its comparison in the columns of a register in which the tattoos, marks, and scars of deserters, etc., were entered. The register consists of two volumes, one for the blue eyed, the other for the brown-eyed men, and is divided, according to height, as follows: 64 inches and under, 64½, 65, 65½, 66, 66½, 67, 67½, 68, 68½, 69, 69½, 70, 70½, 71, 71½, and over. Each register is ruled in columns for the various regions of the body as "Anterior, Posterior, Right, and Left," for the general divisions, with head, neck, shoulder, thorax, abdomen, groin, hip, thigh, knee, leg, ankle, foot, toes, etc., for the specific locality. Each section of height is again divided, and men having tattoos are entered apart from those having no tattoos, for a deserter having tattoos is very likely to have the same when re entering the service, and a recruit coming in without tattoos is not likely to be found among those with tattoos. It will be observed, however, that recruits coming in with tattoos are examined over those deserters who did not have such marks, as these different devices might have been put on while at liberty.

The abbreviations used in entering descriptions of deserters are almost self-explaining, as: V., vaccination; S., scar; T., tattoo; B., birthmark; M., mole; S.P., small-pox; C.P., chicken-pox; etc.

In examining recruits over the register, an inch on each side of the recorded height is allowed for variation or defective measurement.

Much difficulty was experienced, as has been said, in

obtaining accurate cards from the recruiting officers, and a similar difficulty was encountered in procuring prompt information of desertions, so that although the outline figure card was called for on April 1, 1889, it was really not until the beginning of the present year that the system was in proper working order. Nevertheless our results to May 31st last are as follows: twenty-six deserters have been identified, twenty-one men have been recognized as ex-convicts, and twelve as fraudulent enlistments, having been previously discharged for cause, making a total of fifty-nine detections by the body marks. Indeed, the list comprises sixty two cases; and it is to be observed that in this number of cases only one mistake has been made. This was one in which identity was suspected and reported on height, color of eyes, and the loss of a portion of his ear; but the identity was disproved by other circumstances not, at the time of the report, known to this office. The two other cases were successes so far as the system is concerned, for one was a military convict, whose re-enlistment had been authorized, and the other a case of an unsuccessful applicant for enlistment whose card had been forwarded by mistake, compared and identified as a recently released convict.

Upon the result of this experiment, sixty-two cases with but one mistake in so short a time after the inauguration of the system, under many official difficulties, we claim that the body marks, if carefully noted, suffice to determine identity wholly irrespective of the special measurements on which the Bertillon system is based.

[The paper was accompanied with copies of the cards, by which identity was established, and the plan of the register of desertions.]

THE LOCAL TREATMENT FOR SYPHILITIC MANIFESTATIONS OF THE THROAT.

By E. HARRISON GRIFFIN, M.D.,

ATTENDING SURGEON OF THROAT AND NOSE DEPARTMENT OF BELLEVUE HOSPITAL OUT-DOOR POOR, NEW YORK.

Syphilis has generally been looked upon and considered an affection of the skin, and when treated by a specialist the patient usually comes into the hands of a dermatologist.

The skin symptoms are self-limiting in the majority of cases, and this is especially true of the secondary symptoms. What we have to treat mostly in a patient suffering from this disease is not the skin, which generally takes care of itself, but the mucous membrane of the throat, nose, eye, and in fact any portion of the body where nature has distributed this covering.

During the first months of a syphilitic course of treatment the patient will complain mostly of his throat; little mucous patches will appear every now and then and be a source of annoyance, both to the patient and his physician, on account of their repeated and unexpected occurrence. They are the Alpha and Omega of syphilis.

Long after the body has been freed from its symptoms, and the general surface of the skin is as normal as before the patient received the infection, these little patches will again and again reassert themselves.

The patient is much worried over their appearance, as he has been told by his physician that he can convey a chancre by kissing, or by any direct contact of this membrane, to an opposite party. He knows that drinking out of a glass and then offering it to another may communicate this disease. Having his handkerchiefs washed is another means of communication, and smoking a friend's pipe is still another.

Thus the appearance of these small sores in the region of his mouth means a visit to his doctor. The occurrence of these sores can be often traced to the condition of the teeth in a patient's mouth. A jagged tooth will irritate the tongue and produce one of these lesions. The use of tobacco, either in chewing or smoking, will do the same; highly seasoned food is yet another cause. Biting of the lips by the teeth will make a nasty sore, and will produce some of the ugliest mucous patches that a practitioner is called upon to treat. The causes of these patches, we can see, are numerous and varied, and a patient never goes through this disease without finding himself worried again and again by the presence of these symptoms.

Later on in the disease we find the superficial ulcer, deeper than the mucous patch, more likely to spread, more destructive of tissue, but less infectious.

Last of all of the lesions of the mucous membrane we come to the deep ulceration, which may spread and destroy the anatomy of the throat with a remarkable rapidity.

I saw a young man not long ago who had lost most of his tongue; the pharynx was one large ulcer and the roof of the mouth had been entirely eaten away by the ravage of this disease, so that the finger could be passed through his mouth into the nares. The mucous membrane of the cheeks participated in the ulceration.

In looking over this paper for a moment, I think it can be discerned at a glance that it is mucous membrane and not the skin that participates mostly in the ingress of this disease.

It is seldom we are called upon to treat the skin manifestations of this disease beyond a month, or, at the worst, three or four, except in late tertiary cases; but the mucous membrane we must watch diligently and thoroughly throughout course of treatment. It is to the mucous membrane we direct our attention to see the effect of our medicine, and also to the mucous membrane to watch the progress of our patient. If the gums are red or swollen we vary our treatment; if the breath has a fetid smell, again we vary our medication; the mucous membrane is the talisman throughout this disease.

Mucous patches have been destroyed by the application of caustics and cautery; but if the cause of these patches has been neglected, the symptom is sure to reassert itself.

To search for the cause of this lesion and eradicate it would be a good action, but it is easier said than done. There are few patients that will bow down to a physician's directions after their disease is once ameliorated.

Treatment with caustics means repeated applications, to destroy these lesions. The superficial ulcerations and the deep ulcerations of the throat have been treated by blowing on their surfaces powdered iodoform. If we would stop for one second and think, we would soon see that the iodoform is washed off the affected part almost as soon as it is applied. Thus we gain nothing by this mode of treatment.

Iodoform has been applied in ether by means of a spray, but I think this is hardly more efficacious. I sometimes apply it after the following procedure: First, I spray on the part a preparation of some oil, such as the Voschano or benzoinol, then blow on my powder and again spray with the oil; thus the part is covered evenly with a perfect unguent. This sometimes is very satisfactory, as the oil seems to hold the powder blown on, and to prevent partially the saliva from removing it.

A number of washes have also been used for the treatment of these various throat manifestations—carbolic acid, Dobell's solution, various strengths of chlorate of potash, and many other formulas.

Lately I have used, with a most pleasing and beneficial result both to myself and to my patient, the ordinary lotio nigra.

Mucous patches that defied extirpation with other medication have disappeared rapidly and permanently when this solution has been used according to my directions.

I no longer look at these lesions as the bugbear of syphilis. I have found this preparation a most useful and satisfactory agent in the treatment of these throat affections.

Patients that in the past would see me weekly, complaining of one of these sores, now go months, and in the majority of cases, where the internal treatment is also followed out, I have failed to observe any of these unpleasant symptoms.

I employ this wash for the mucous patch, the superficial ulcer, and the deep and dreaded tertiary lesion. It acts marvellously well in all three, much better than the carbolic acid, cautery, the iodoform, and any I have ever tried. I have used it most extensively in my Bellevue clinic, and in my private practice. The most afflicted throat will feel its good effect after one or two applications.

A patient who had been troubled with repeated and ugly ulcerations of the tonsils that combated internal treatment alone, and failed with other applications to the mucous membrane, told me that he saw these patches disappear when he gargled his throat with this wash. I rather demurred at his enthusiasm, and when he saw a look of uncertainty on my face, he modified his statement and said: "Well, doctor, if I don't see them heal, I feel them heal with every application." This is a pleasant thing to be told and a pleasant thing to see.

We have in this simple wash a specific for this class of throat affections. I also use it through a spray in treating ulcerations of the mucous patches of the larynx.

These cases should be seen oftener by the practitioner, as the patients are unable to bring the wash on the diseased parts. Ulcerations in this location are sometimes most unique in their history.

I had a woman apply to me at the clinic, complaining of a tickling in her throat, and absolutely having no pain. An examination revealed extensive ulceration of the true and false cords, the epiglottis, and a general and extensive ulceration of the whole lining membrane of the larynx. The ulceration was so situated that the patient's voice was not altered one particle from its normal register. The volume and the tone were perfect. She did not know that she had a sore throat in the neighborhood of her larynx until I told her. She felt no pain, no loss of voice, and not the slightest indication of a laryngeal trouble. It was an isolated case.

The ulceration seemed to be so situated that the speech was not altered. Inside of a week her epiglottis might have been permanently destroyed and the voice greatly impaired.

Syphilis of the mucous membrane is a most insidious disease. We must watch our patient carefully, no matter how well he may appear, throughout a course of treatment.

To the mucous membrane we direct our eye to see how the syphilitic virus is being conquered, and often we can diagnose a past syphilis, even when the patient is most emphatic in a denial of any past contamination.

A diligent search of the mouth of an old syphilitic, where he has ever had any tertiary ulcerations of the throat, will reveal little cicatrices, in some cases so small that they would be readily overlooked; but to an experienced eye they would be as diagnostic of this disease as the sub-crepitant râle, when heard in the apex of a lung, is of phthisis. These little marks will unfold a history, and we can tell sometimes by their appearance about how long ago the patient had his first chancre.

Sometimes a scar will be seated high up on the hard palate, other times on the soft, perhaps a small mark on the uvula, other times on the lips. No matter how firm a patient may be in his denial of any past infection, the presence of these marks generally means that an old tertiary sore has been healed.

The pain in these ulcerations is usually very slight. We must differentiate between pain and an annoyance. Pain is present in tuberculous ulceration of the throat, but rarely syphilitic ulceration, no matter how extensive the ulceration may be.

Patients when they apply to the practitioner will complain of pain; but if we ask the patient if he suffers more when he is eating or drinking, he will generally reply, "I have some trouble in getting my food past my throat," and he will point with his finger usually to his thyroid cartilage, which will mean, in the majority of cases, that the epiglottis may be congested or inflamed and of course impedes the entrance of food into the œsophagus. It is not a pain. If it was it would be painful when he ate or drank, but when he is so engaged the throat is generally much relieved.

In laryngeal phthisis the pain at this time is so intense that the patient in this disease dies of starvation or chokes to death, as the pain is so great that he has not the ability to eat.

In syphilis, if we bind our patient to it, even if we find the epiglottis is almost destroyed, we find that there is no actual pain, but that there is a difficulty in guiding the food to its proper destination.

Syphilis is not confined to bachelorhood. Cases will come up under our observation where the parties are married. Here we must watch the throat as assiduously as we did the chancre. The slightest mucous patch will imprint the infection on a person's partner.

A young man saw me some three years ago with one of these sores and gave a history of being married five weeks. I cauterized the membrane and appointed two days after for a second visit. I did not see him again till three weeks had elapsed, when he appeared with his wife, who had a chancre on her lip, caught by kissing him upon his mouth. If the patient is married we cannot watch the throat too carefully. We should interdict all kissing until we are well assured that the patient's system is well under the control of internal medicine and the mucous membrane fails to disclose any of these patches.

Mr. A——, aged twenty three, applied to me, complaining of a sore throat of four weeks' standing; he had been taking internally a mixed treatment. An examination disclosed an extensive ulceration of the pharynx, the soft palate on one side had been destroyed up to the hard palate. The membrane was very much congested and inflamed, and the ulceration seemed to be spreading with a remarkable rapidity. I put him under large doses of potassium iodide and the local use of the lotio nigra as a gargle five times a day. The following day he reported the throat much easier, his cough had decreased in its intensity, his expectorations much freer, and the general symptoms much decreased. In two weeks the throat was completely healed.

Patient B—— applied to me complaining of tenderness of the tongue, and an examination showed the whole organ covered with mucous patches. He had been taking internal medication. I put him under the French protiodide pills and the local use of the wash. In little over a week the throat presented its normal appearance, although I did not interdict his smoking. At this time he was consuming three or four cigars a day. He had been troubled with these patches for the past six months. After the throat was healed I directed him to use the wash diluted one-half strength every night and morning, no matter whether his throat was sore or normal. Five months have now elapsed and he has had no outbreak of any of these lesions.

Case C—— applied to me with a sore nostril, and an external examination revealed a heavy ulceration of the external nose extending up to its junction with the nasal bones. The lower portion of the nose had been completely destroyed and eaten away. The septum and all the nasal bones had necrosed and had disappeared long before the lady paid me a visit. The inside of the nose revealed one large and extensive ulcerated surface. I put her under internal medication and had the nose washed out five times a day with lotio nigra and treated also with the iodoform ointment. In a few days the case was absolutely under control and in a little over four weeks the parts had completely granulated. I could not have obtained this quick result if it had not been for

my local applications. I could cite case upon case of this tertiary ulceration that have yielded most marvellously under this simple local treatment, and I see every day in my office cases where the throats present a normal appearance, free from any mucous patch, due to the use of this wash night and morning, although some of the patients are addicted to the use of tobacco. In some instances the wash will have to be diluted one half strength; but if the symptoms are severe, it is best to adhere to the regular formula. With this mode of treatment a practitioner can control the most obstinate case of syphilis and in time eradicate the poison entirely from his patient's system.

112 West Forty-fifth Street.

A CASE OF DROWNING WITH RESUSCITATION.

By F. A. BURRALL, M.D.,

NEW YORK.

As is usual at this season, casualties from drowning are of frequent occurrence. No class of emergencies is of a more startling character, and I think that a history of the case which I now present offers some peculiar features, and will not be without interest to physicians.

The accident which forms the subject of this paper occurred August 29, 1890, at South Harpswell, Casco Bay, Me., where I was passing my vacation.

At about 9.30 A.M., M. B——, an American, aged eighteen, the son of a fisherman, a young man of steady habits and a good constitution, with excellent muscular development, and who had never before required the aid of a physician, was seen by the residents of the village to fall forward from a skiff into the water and go down with uplifted hands. I could not learn that he rose at all after the first submersion. Two men were standing near a bluff which overlooked the bay, and after an instant's delay in deciding that an accident had occurred, they ran over an uneven and undulating pasture for a distance of two hundred and fifty paces to the shore. One of them, after a quick decision not to swim out to where the young man had fallen in and dive for him, removed trousers and boots and waded out five yards to a boat which he drew in to the shore and entered with his companion, taking him to a yacht which lay two hundred and forty yards from the shore, in the padlocked cabin of which was a boat-hook. The padlock was unfastened, the boat-hook taken, and they proceeded by the boat directly to where the young man lay. He was seen through the clear water, lying at a depth of nine feet at the bottom of the bay, on his back, with upturned face and arms extended from the sides of the body. He was quickly seized by the boat-hook, drawn head upward to the surface, and with the inferior portion of the body hanging over the stern of the boat, and the superior supported in the arms of his rescuer, was rowed rapidly to the shore, where he was rolled a few times, and then placed prone upon a tub for further rolling. I was told that much water came from his mouth. Meantime I had been sent for to where I was sitting, one hundred and fifty-one yards from the scene, and I arrived to find him apparently lifeless on the tub, and to be addressed with the remark, "Well, doctor, I suppose we are doing all that can be done."

I have given these details, as from a study of them I was aided in deciding the time of submersion, as well as the intervals which transpired before the intelligent use of remedies. It is also remarkable that, notwithstanding all which has been written about ready remedies for drowning, no one present knew anything about them, although living in a seafaring community.

I immediately directed that the patient should at once be placed upon the ground, which was sloping, and arranged his rubber boots under the back of the head and nape of the neck, so that the head should be slightly elevated and the neck extended, while the head was turned somewhat upon the side, that fluids might drain from the mouth. The day was clear and moderately warm. Respiration had ceased, but no time was lost in commencing artificial respiration. The patient had on a shirt and pantaloons, which were immediately unbuttoned and made loose, and placing myself at his head I used the Sylvester method, because I was more accustomed to it than any other. It seems to me more easy of application than any other, and I have often found it of service in the asphyxia of the newly-born.

The patient's surface was cold, there was extensive cyanosis, and his expression was so changed that he was not recognized by his fellow-townsmen, but supposed to be a stranger. The eyelids were closed, the pupils contracted, and the inferior maxilla firmly set against the superior. One of the men who had brought him ashore had endeavored to find the heart's impulse by placing his hand upon the chest, but was unable to detect any motion.

I continued the artificial respiration from 9.45 until 10, when I directed one of his rescuers to make pressure upon the ribs, as I brought the arms down upon the chest. This assistance made expiration more complete. When nature resumed the respiratory act I am unable to say, but the artificial breathing was continued in all its details for three-quarters of an hour, and then expiration was aided by pressure on the chest for half an hour longer. Friction upward was also applied to the lower extremities, and the surface became warm about half an hour after the beginning of treatment.

About twenty minutes after ten, two hypodermic syringefuls of brandy were administered, but I did not repeat this, since I think alcohol is likely to increase rather than diminish asphyxia, if given in any considerable quantity. A thermometer, with the mercury shaken down below the scale, at this time did not rise. At 11.8 the pulse was 82; respiration, 27; temperature, 97.

After natural respiration had commenced, the wet clothing was removed, and the patient was placed in blankets. Ammonia was occasionally applied to the nostrils, since, although respiration had returned, there was no sign of consciousness; the natural respiration was at first attended by the expulsion of frothy fluid from the lips, which gradually diminished, and auscultation revealed the presence of a few pulmonary râles, which also passed away. There were efforts at vomiting, and pallor succeeded cyanosis; there were also clonic contractions of the flexors of the forearm. The pupils dilated slightly at about one hour after beginning treatment. Unconsciousness was still profound, and loud shouting into the ear elicited no response. Mustard sinapisms were applied to the præcordium, and the faradic current to the spine.

Coffee was also administered by a ready method which, as a systematic procedure was, I believe, novel when I introduced it to the profession in the Medical Record, in 1876. I take the liberty of referring to this, since I think it is now sometimes overlooked. It was described as follows:

"A simple examination which anyone can make of his own buccal cavity will show that posterior to the last molar teeth when the jaws are closed, is an opening bounded by the molars, the body of the superior, and the ramus of the inferior maxilla. If on either side the cheek is held well out from the jaw, a pocket, or gutter, is formed, into which fluids may be poured, and they will pass into the mouth through the opening behind the molars, as well as through the interstices between the teeth. When in the mouth they tend to create a disposition to swallow, and by this method a considerable quantity of liquid may be administered."

After I had worked with the patient in the open air, for four and three-quarter hours, he was carried to a cottage near by and placed, still unconscious, in bed. There had been an alvine evacuation during the time in which he lay in the blankets.

Consciousness began to return in the early part of the following morning, and with its advent it was discovered that the memory of everything which had occurred from half an hour previous to the accident, up to the return of consciousness, had been completely obliterated. With this exception the convalescence was steady and uncomplicated, and of about a week's duration. From a letter which I recently received from my patient, I learned that the lapse of memory still remains.

My experience with this case has taught me that, unless the data have been taken very accurately, we cannot depend upon any statements as to the time of submersion in cases of drowning. My first supposition was that my patient had been from thirteen to fifteen minutes under water, but a careful investigation reduced the supposed time by one-half. This makes the time of submersion about six minutes, and that which elapsed before the intelligent use of remedies about three minutes longer.

For a long time the opinion of Sir Benjamin Brodie, concerning the presence of water in the lungs of the drowned, was accepted, who says "that the admission of water into the lungs is prevented by a spasm of the muscles of the glottis cannot, however, be doubted, since we are unable to account for it in any other manner."

Later experiments made by a committee of the Royal Medico-Chirurgical Society of London demonstrated, on the contrary, "that in drowned animals not only were all the air-passages choked with frothy fluid, more or less bloody, but that both lungs were highly gorged with blood, so that they were heavy, dark-colored, and pitted on pressure, and on being cut exuded an abundance of blood-tinged fluid with many air-bubbles in it." Dr. R. L. Bowles [1] also holds that the lungs of the drowned contain water, and supports his views by a list of cases. In his words, "These examples show very conclusively that in cases of drowning in man, water does exist in the lungs, that the water only very gradually and after a long time is effectually expelled, and that it is absolutely impossible that any relief should be afforded in that way by the Silvester method." Dr. Bowles believes that the method of Dr. Marshall Hall is superior to any other in this class of cases. He thinks that on account of the immediate adoption and continued use of the prono-lateral position, this method is more to be trusted than any other for keeping the pharynx clear of obstruction. "It also empties the stomach and gradually clears the lungs of the watery and frothy fluids, and will surely and gently introduce sufficient air at each inspiration to take the place of the fluid which has been expelled." In the light of even my limited experience I cannot but feel that Dr. Bowles's opinion concerning the Silvester method would admit of some modification. This is often the case with very positive statements concerning medical matters. In my own case the Silvester method answered well, but I was much impressed with Dr. Bowles's claims for the Marshall Hall method, and should bear them in mind were I called upon to attend another case of drowning.

I think it must be admitted that pulling the tongue forward as a means of opening the glottis, which has become a standard treatment in asphyxia, is unscientific, and not warranted by the results of experiments made to determine its value.[2]

Dr. Bowles also believes that "the safety of the patient is most perfectly secured by keeping him on one side during the whole treatment, one lung being thus kept quite free." With the account of my case I have brought forward such views of other writers as it seemed to me would be of practical service and throw light on a subject which is of great importance, since the yearly record of mortality from drowning is by no means inconsiderable. I think, however, that a knowledge of what ought to be done in cases of drowning should be much more generally diffused than is the case at present. It should be one of the items of school instruction, since no one can tell when such knowledge may be of immense importance in saving life, and the time lost in securing medical aid would involve a fatal result.

It is also very desirable that all doubt should be removed, by the decision of competent medical authorities, as to which "ready" method or methods are the best, since there are several in the field. With this should be decided what is the best means for securing patency of the air-passages, and, in short, a very careful revision of the treatment now recommended for drowning, in order that there may be no doubt as to the course which should be adopted in such a serious emergency.

[2] Dragging on the tongue's tip would not affect its base or the epiglottis sufficiently to make it a praiseworthy procedure. Medico-Chirurgical Transactions, vol. lxxii. See also MEDICAL RECORD, April 4, 1891. Pulling out the tongue is a mistake, since irritation of nerves of deglutition stops the diaphragm. Medical Times and Gazetteer.

A FEW REMARKS ON THE TREATMENT OF LAMELLAR AND SENILE CATARACTS.

By G. HERBERT BURNHAM, M.D., F.R.C.S. Edin., M.R.C.S. Eng., Etc.,

LATE RESIDENT SURGEON TO MOORFIELDS EYE HOSPITAL, LONDON; OCULIST AND AURIST TO THE EYE AND EAR INFIRMARY AND THE GENERAL HOSPITAL, TORONTO, ETC.

The lamellar cataract is a peculiar, and, as a rule, an easily distinguishable form. The oculist is generally consulted on account of dimness, or increasing dimness, of sight, not relieved by glasses selected by the patient, or supposed short-sight. The vision should always be carefully tested. A hasty test may give comparatively poor vision, whereas a careful one will show a little astigmatism, which, when corrected, is followed by greatly improved sight.

The operations usually performed are needling, with or without the subsequent use of the curette or syringe. I may mention that in this form of cataract I consider that the manner of needling the lens is of very great importance. When discission is alone to be used there should be at first only moderate laceration of the anterior capsule, with very little disturbance of the adjacent lens substance. By doing this the patient can be sent away with safety, as the soft matter affected by the aqueous comes away readily through the opening into the anterior chamber, and thereby does away with the fear of tension, the chief danger. This, of course, means frequent repetition. The oft-repeated needling and slow absorptive process consequent upon this operation are the chief objections to its employment.

The other method is, I consider, much preferable and not any more dangerous, when properly performed. Here, on the contrary, the needling is to be freely done, and in its improper performance lies the greatest source of danger. A moderate amount of the anterior capsule ought to be lacerated, together with the adjacent lens substance, to a fair depth, so that it may not only be freely reached by the aqueous, but, when acted upon, readily make its way into the anterior chamber. Thus tension and pain are avoided, and the cataract is removed in a short time. Even if there should be a little pain, as long as there is no plus tension it need cause no alarm; but if tension, then great watchfulness should be exercised. In some cases a marginal corneal incision and the use of the curette to keep apart the lips of the wound allow a great deal of soft matter to escape. However, as a rule, the use of the syringe does so more fully. In using this latter, guard against drawing into it any part of the vitreous or iris. With care neither of these complications should occur, and hence should not be looked upon as momentous objections. If the needling be done by making merely a small opening in the capsule and then freely disturbing the lens substance, evil is almost certain to follow. The lens swells with great rapidity, so that in two hours severe pain and marked plus tension are noticed. The tension must be removed at once, either by tearing

freely the capsule or extracting the lens by a corneal incision. To allow these symptoms to remain without such prompt measures of relief means purulent cycloiritis in a few hours, with diminished tension and the loss of the eye. The after-treatment consists of the use, locally, of atropine, ice, and leeches, if necessary.

If before the operation very good, though misty, vision can be obtained by glasses, I have seen the patient very greatly pleased by operating upon one eye and leaving the other untouched. In this way clear perception after correction by glasses is got with the eye operated upon, and the other, with its fair vision and normal accommodation, is a much better helpmate than if it had been operated upon. I remember well a young physician upon whom this was practised with great convenience and satisfaction to himself.

Of the methods of removal of the ordinary senile cataract the operation I consider the safest is that in which a preliminary iridectomy is done with subsequent removal of the lens; next, the removal with iridectomy at the time of the operation; and finally, the extraction without iridectomy. For either of the two prior methods the position of the corneal incision close to the periphery, with a small conjunctival flap, is the best, as it not only hastens and strengthens the union of the wound, but also renders it less liable to leak and to purulent infiltration. Free laceration of the capsule corresponding to the pupillary centre has a tendency, I think, to lessen the necessity of subsequent needling. Dr. Knapp's method of peripheral laceration of the capsule has certain features which commend it, but at the same time the objection of always requiring secondary needling. This needling, though very rarely fraught with bad results in skilful hands, still is an operation which every oculist is desirous of escaping. It is advisable to clear the wound by the use of the forceps or vulcanite spatula, not by sponges or absorbent cotton. The five per cent. lotion of muriate of cocaine seems to be about the best strength. It is always very necessary to see that the edges of the wound are well coapted, and that no coagulæ lie between them. If there should be left much soft matter, use atropine immediately after the operation. The danger of prolapse or anterior synechia is not at all increased, I am persuaded, and the tendency to iritis and the consequent thickening of the capsule is much lessened. Eserine is only to be used when the iris cannot be made to fall back into its place, and then stopped in twenty-four hours and atropine substituted.

As to the propriety of looking at the eye after extraction, examine it at any time if you are in doubt as to its condition; for by telling the patient quietly to open both eyes, it will be done easily without any spasmodic movements. In this way the eye is seen, the face not even being touched by the fingers.

The extraction without iridectomy is, in soft or fluid cataracts, thoroughly justifiable and gives good results. In the ordinary hard senile cataract it seems to have greater drawbacks than the other methods. It requires a purely corneal incision, the iris is subject to much greater bruising, and, besides, the danger of prolapse of the iris is much increased. The use of eserine to act on the iris brings the latter into closer contact with the soft lens matter left in the eye, and thus renders iritis much more likely to occur. As to vision, I do not consider there is much difference; and as to appearances an ordinary observer would not remark the presence of an iridectomy, as the upper eyelid and thickness of the lens prescribed render it far from noticeable.

I have frequently had patients with miniature cataracts come to me, saying, "One of my eyes is now so dimsighted that it must be ready for operation, and as to the other, the cataract is pretty ripe." This condition was really miniature cataract in each; but in the blind eye the dimness was due to long-standing chronic glaucoma. Seeing this so often has caused me to advise, in eyes likely to be so affected, a preliminary iridectomy, so as to take all possible precautions.

In purulent infiltration of the wound I introduced the use of the five per cent. lotion of carbolic acid, which acted most successfully. Now, however, the same principle is carried out by the bichloride of mercury lotion. As to the preparation of the eye for operation, I do not see any utility in so thoroughly flushing an eye with antiseptic lotions as some do. If the eye be a normally healthy one, I think the conjunctiva is irritated by such a procedure. If, however, there is an unhealthy condition, then, if compelled to operate, use them, but then only. It is to the instruments I should give great attention, and see that beyond all doubt they are aseptic.

At Moorfields Eye Hospital we paid great attention to this. They, just prior to their employment, were taken out of a five per cent. lotion of carbolic acid and so placed that the part of the instrument coming into contact with the eye was held up by a little cross-bar on the tray, so as not to touch anything. By doing this, by examining the condition of the conjunctiva and lachrymal apparatus, and by the surgeons washing their hands before operating, purulent infiltration became very rare indeed, though many of the patients seemed good subjects for it as far as general appearances went. I am quite well aware of the strong feeling of some oculists as to the necessity of antiseptic washing of the eye just before operating, but I must confess, in the healthy eye, this seems to me meddlesome surgery.

By making an alteration in the Graefe knife I think I have added to its usefulness. I speak of the Graefe knife made by Weiss & Son, London. The change consists in having placed the broad side of the handle at right angles to the broad side of the blade, instead of in the same plane as at present. This change enables the finger-tips so to grasp the flat surface of the handle as to give much greater tactile power and freedom of movement. I have used it for several years with ever-increasing benefit and to the exclusion of the old form.

Clinical Department.

NECROSIS AND SPONTANEOUS RESECTION OF THE HEADS OF BOTH HUMERI.

By H. W. NELSON, M.D.,

STEUBENVILLE, O.

THE following case is, I think, a very good practical illustration of the conservative powers of nature.

Lena O——, aged seven, was attacked, October 8, 1889, with what was supposed to be acute articular rheumatism. She is of healthy parentage. There is no history of hereditary taint or tendency to disease, specific or otherwise. Neither is there any history of traumatism or of exposure to atmospheric influences. Her previous health seemed to be good. She came home from school complaining of being tired and weary. During the night she was feverish and very restless, complaining of soreness and pain in her limbs, especially her shoulders. In the morning her shoulder-joints were very much swollen and very painful. The case was regarded by the attending practitioner as one of articular rheumatism. In a short time all the joints of both the upper and lower extremities were involved to a greater or less degree. The attending practitioner informed me that she had intense pain, high fever, and very great restlessness. About the seventh day of the attack it was found that ulceration was threatened directly over the head of the humerus. I was asked to see her on January 21, 1890. At that time there existed extreme emaciation, profuse perspiration, diarrhœa, and a feeble, frequent pulse. The joints of the upper and lower extremities were red, swollen, and painful. At the shoulders, wrists, forearms, knees, ankles, and along the anterior surface of the tibia, were ulcerated openings discharging ichorous pus. The little patient was so sensitive and irritable from her long suffering that a satis-

factory examination could not be made. The head of the humerus of each side could be seen and felt through the ulcerated openings. She was ordered cod-liver oil with lactophosphate of lime, and a simple nutritious diet. Medicines were given to procure rest and restrain the diarrhœa and sweating. The head of the humerus being dislocated from the glenoid cavity by the ulcerative process, the whole arm was drawn upward and forward by the action of the deltoid and pectoralis major, causing the bone to protrude more and more. One and a half inch of the left humerus, and one inch of the right, were protruded and exposed. Nature began to resect the exposed portion of bone, and on March 5th it came away. About April 1st a similar portion came away on the other side. The pain and soreness began to diminish, the opening slowly healed, and we began making gentle passive motion of the upper end of the decapitated humerus. The colliquative diarrhœa and sweating ceased, and the patient gained in flesh and strength, and to-day she is in good health. She has almost unimpaired motion at the shoulders, necrosed portions of the bone have ceased to come away, and there is no obvious deformity.

A HAIR-PIN IN THE NOSE.

By JOSEPH C. ROTH, M.D.,

SYRACUSE, N.Y.

On January 28, 1886, while the writer was doing night duty at the Out-Patient Department of Chambers Street Hospital, New York City, a policeman brought in his daughter, stating that she had a hair-pin up her nose, and that a physician had tried for an hour to remove it. Upon questioning how the accident happened, she said she had dry nasal catarrh, and frequently used the curved end of a hair-pin to loosen the crusts. On the evening of January 27th she attempted to cleanse her nose as usual, and introducing the pin too far, it eluded her grasp; all attempts at its removal merely seemed to push it still farther into the nose. On examination I found a hair-pin in the right nostril, the two points embedded in the mucous membrane of the bony septum and turbinated bone. I attempted extraction with forceps for some time, but being unsuccessful, and producing quite a free hemorrhage, I wrapped cotton about a nasal probe, and pressing it against the inner side of the distal or curved end of the hair-pin, pushed it as far into the naso-pharynx as possible. I then, with my index and second fingers passed through her mouth and upward, back of palate, grasped the curved end of the hair pin, and extracted the same through the mouth.

By removing the pin in this manner I was able to avoid all injury to the nose and throat, save what I had done while attempting its extraction through the anterior nares. The hair-pin was of the ordinary shape and size, measuring two and a half inches doubled, or about five inches from end to end.

AN UNUSUAL CASE OF DISLOCATION BY DIRECT VIOLENCE OF COSTAL CARTILAGES UNATTENDED WITH SERIOUS CONSEQUENCES.

By WILLIAM H. ARTHUR, M.D.,

CAPTAIN AND ASSISTANT SURGEON, UNITED STATES ARMY.

James T——, private, Troop F, Tenth Cavalry, young mulatto, had been on sick report several times for trifling ailments, colds, nasal catarrh, acute tonsillitis, etc., since January last, but had never given any history of injury of any kind. On May 23d he came to sick call complaining of a slight pain in the left breast. On stripping the man to make a physical exploration of the chest, a very marked nodular prominence was noticed in the median line, about one inch above the ensiform cartilage. Examination showed complete dislocation forward of the sternal end of the sixth, and a partial dislocation of the fifth costal cartilage on the left side, with partial dislocation of the corresponding cartilages on the right side.

On inquiry the patient gave the following history, for the first time: Early in January he was knocked down and tramped upon by a mule, while shoeing. The breath was knocked out of him, but the pain didn't last long, and he continued on duty. Great swelling came on, and as it gradually subsided the prominence of the dislocated cartilages became apparent.

The patient complains of little or no pain or discomfort, except when making a great effort or trying to lift an unusually heavy weight. No attempt at reduction was made, the difficulty of retaining the displaced cartilages in place, even if they could be forced back, being evident.

FORT GRANT, ARIZ.

THERMOMETRY IN DIAGNOSTIC RELATION TO EAR DISEASE.

By G. STERLING RYERSON, M.D., C.M., L.R.C.S. EDIN.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN TRINITY MEDICAL COLLEGE, TORONTO.

Every aurist must have remarked in the course of treatment of chronic suppuration of the middle ear that there are times when the auricle feels warmer than usual to the hand. I have noticed also that this increased warmth of the ear often corresponds with an increase of discomfort in the ear, and even with pain. It occurred to me to insert an ordinary registering thermometer in the external auditory canal, which revealed the fact that there was an increase of temperature on the affected side of from one-eighth to one degree. When I have found this the case I have used free douching with carbolated hot water, which, in my experience, always relieves subacute congestions and inflammations of the middle ear whether the drum-membrane be perforated or not.

My observations have extended over the last two years, but have not been followed up very persistently or systematically. My attention was drawn anew to this subject by some remarks made at the Ontario Medical Association meeting, which was held recently in this city, by Dr. Birkett, of Montreal. He stated that Dr. Buller had been using surface thermometry to the mastoid with important results, which he will no doubt publish in due time. In the meantime I invite the attention of the profession to this novel proceeding in the hope that it may lead to new indications in diagnosis of deep-seated ear disease.

PURPURA HÆMORRHAGICA.

Dr. T. J. Whitney, of Frewsburg, N. Y., writes: "The report of a case of purpura hæmorrhagica occurring in practice is as follows: An old man, aged ninety-one, has suffered three attacks, each time in the spring of the year. There was venous oozing from all the mucous surfaces—bladder, bowels, mouth, and nose—the skin being covered throughout the body with specks and spots from the size of a pin-head to that of the hand. There was constipation of the bowels with a congested portal circulation, and consequently the whole venous system was engorged. As the patient was suffering from 'senile obstinacy' and would take no medicine, I made the remedy fit the disease and gave him gtt. ij. of croton oil, suspended in milk, which he was willing to take every two hours until he was thoroughly purged. The result was immediate relief and a cure of the trouble within five days."

Dr. Concepcion Aleixandre has recently been appointed upon the staff of the Hospital de la Princesa in Madrid. This is said to be the first appointment of a woman to any official position in Spain.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 22, 1891.

MEDICAL OFFICERS OF PASSENGER STEAMSHIPS.

ONE of the trials of the Health Officer of this port, and probably of those at other ports as well, though to a less degree, is the trouble and the vexation caused by the utter incompetence of many of the surgeons supposed to look after the health of the passengers and crew of the vessels on which they sail. In his previous reports Dr. Smith, the Health Officer at New York, has protested against this state of things, and urged the necessity of devising some way by which it may be possible to secure competent men for these responsible positions, and in his report for this year he again devotes several pages to the subject.

In spite of what has been said by many conversant with the existing evils of the medical service on the passenger steamships coming from Europe to this city, it is reported that there has been no material change for the better, and that there is not likely to be until the companies awake to the fact that it is to their own interest to obtain good men for this service by the only way in which this is possible, namely, by paying their doctors a salary that will compensate them and will attract experienced and intelligent men, who will take up the work for life, and not merely as a little vacation after student days, and with a desire to see something of the world before settling down to the routine work of medical practice. The fact that the surgeons on the first-class transatlantic steamers are generally good men is evidence sufficient that the payment of a fair salary would bring men of ability into the service, since on these boats the contributions of the passengers add sufficiently to the miserable salary paid by the company to make the position a desirable one, and to attract physicians of some standing in their profession. But even here, as Dr. Leet, of Liverpool, has so often declared and proved, it will be impossible to get men who will act solely for the good of those entrusted to their professional care, when possibly the health and well-being of these people can be secured only at some pecuniary sacrifice on the part of the company, or it may be at the expense of the captain's comfort, until the surgeon is made in a measure independent of the company for his position. "The medical service on transatlantic passenger steamers, will never be what it should and can be," says Dr. Smith, "until the medical officer has a status in the mercantile marine which he has reached by due preparation and examination by a competent board, and which will be as secure and permanent, when he has obtained it, as that of the medical officers in the English navy, or the United States Marine Hospital service."

It would at first seem a rather hopeless task to induce these companies, whose margin of profit is none too great, to increase their expenses sufficiently to enable them to offer a compensation that will tempt competent men to accept service under them in their ships. But it might be found cheaper in the end, if by so doing the occasional detentions at Quarantine, necessitated by blunders on the part of the ship's surgeon, could thereby be done away with. In one case a passenger who had been suffering from small-pox for four or five days was found by the deputy health officer on making his inspection at Quarantine. This case had not been seen, or at least not recognized, by the ship's doctor. The passengers were removed to the Quarantine of Observation and detained fourteen days, at an expense to the company of about four thousand dollars. This sum, added to the amount now paid to the medical officers of that line, would have made each one's salary nearly decent, and there would have been some inducement to educated and competent men to enter the employ of the company.

The gross stupidity of some of the surgeons to whom are entrusted the lives of travellers to and from England and the Continent, is most astonishing. An instance illustrating this, which occurred on an English steamer arriving at Quarantine with six hundred immigrants, one of whom had small-pox, is related by the Health Officer of the port in his report. "The patient was found in a sort of box seven or eight feet square, built of rough boards in the centre of one of the steerages. For purposes of ventilation a hand's breadth of space was left on all sides at the bottom of the pen, and some five feet from the bottom slats were laid horizontally, two or three inches apart, until the sides were built up sufficiently high to prevent the escape of the patient, or the intrusion of friends. When the Health Officer remonstrated with the doctor for this outrageous exposure of the well passengers to the contagion of the sick, he exclaimed, in words and with a manner that seemed intended to settle the matter, 'Don't you see, sir, that I have scattered carbolic acid powder all around?' pointing to a patent disinfecting powder that had no effect except to disguise more disagreeable smells, that had been sparingly scattered on the steerage floor in the vicinity of the victim's pen." Another so-called doctor allowed a passenger with semi-confluent small-pox to remain four or five days in the steerage with four hundred and twenty-eight other passengers, apparently not knowing that there was anything wrong with the patient.

But all are not as bad as this, and since we have quoted Dr. Smith in some of his strictures upon the incompetent, we gladly listen to him when he finds something pleasant to say for the efficient among the ship surgeons. "There are," he says, "capable and efficient medical officers on those transatlantic passenger steamers whose patrons are numerous and liberal; to such these criticisms do not apply; and for those they are not intended. There are few more capable physicians than many of the medical officers of the first-class steamers that run between ports of the Old World and the New."

SHOULD YOUNG DOCTORS WRITE?

When a young man begins his medical career the question sometimes arises whether he ought to write articles for medical journals. The first and instinctive response is in the negative. He has had but little experience, and he cannot possibly add anything to the sum of medical knowledge. But this view of the matter is, in fact, not entirely correct. For, in the first place, the capacity for literary work, and of putting ideas in written words has to be developed early in life. To the vast majority of men writing is a mighty task because the habit was never acquired during the plastic season of youth. If a man does not begin to write before he is forty he will never do it at all. The practice of writing, therefore, though it may be acquired at the expense of a good deal of indifferent work, helps the physician in his maturer years to embody results that are of great importance and interest. There are, as everyone knows, in all large cities a number of medical men of brilliant attainments, large experience—acute, practical, and successful. But they cannot write; and the profession is but little the better for their labors. Usually such gentlemen speak lightly of literary work and do not believe in "rushing into print." As a matter of fact they only do not do it because they cannot.

The kind and amount of literary work which young men can wisely undertake is limited, and this fact should be steadily borne in mind. Reporting cases must be done very little. The case should either be unique in kind or of positive interest therapeutically or pathologically. Experimental work in physiological or pathological laboratories is a kind always open to young men, and almost always gives results in some increment to medical knowledge.

A field of literary labor also in which young men can usually work profitably is that of collating and digesting critically all contributions upon certain subjects. Such articles, if prepared carefully in connection with personal observations, are often of great service to older and busier men.

Many young men make the mistake, in pursuing a certain task, of attempting to prove too much or of investigating too wide a field. It is much better to settle a little matter positively and forever, than to bombard a large subject with inconsequential results.

Finally, we would remind young men that therapeutical problems are the most difficult to solve; and that books should never be written by the immature.

WHAT ANTISEPSIS HAS DONE.

The younger generation of surgeons, whose medical birth and bringing up date back no more than ten or a dozen years, have little conception of the trials that beset surgeons before the discoveries of Pasteur and Lister and the results that have flowed from them. As little, perhaps, as those of older growth have of the ante-anæsthetic times, when patients were poisoned with tobacco in order to produce muscular relaxation and were strapped to the table to keep them quiet while under the surgeon's knife, and when skill and speed were nearly synonymous terms in recounting the qualifications of an operator. We compare the results now obtained with those of fifteen or twenty years ago and are prone to forget the tremendous advantages we have, and to plume ourselves with scant reason on being better surgeons than we were in those days or than others were before us.

These reflections have been called forth while reading Sir James Paget's "Studies of Old Case Books," to which we have already referred in these columns, and observing the fatal course of many cases which nowadays would scarcely be looked upon as in any sense serious or demanding more than ordinary care and attention on the surgeon's part. We may believe that the author's cases could nowhere have received better care than they did in his hands, yet he relates a number of instances similar to the following in which a fatal termination in these days would seem almost inexcusable. The case was one of abscess, which was opened and discharged a large amount of pus ". . . and then the case went on after the usual manner of the time, near thirty years ago, and the patient died about five months after the accident, exhausted with suppuration, hectic, blocked femoral and iliac veins and bed-sores."

In almost any surgical work of those times and in the files of old journals the same story can be read. It was not that the surgeons were incompetent, far from it, for there were giants in those days, but because asepsis and antisepsis were unknown and unpractised. We certainly have cause to congratulate ourselves and our patients as well, or more, that we live and work in the days of anæsthetics and of antiseptics. But who would not give much for a peep ahead to see what surgeons of fifty years hence will be doing, what wonders they will be able to accomplish, and what by us undreamt-of methods will then be in daily and hourly use?

News of the Week.

The Medical Editors of the United States are invited to a conference to be held in St. Louis during the meeting in that city of the Mississippi Valley Medical Association, on October 14th, 15th, and 16th. Dr. Love, Chairman of the Committee of Arrangements of this Association, extends invitation to all physicians who are eligible to membership in the American Medical Association to come to St. Louis at this time and enter into the scientific work and social pleasures of the occasion.

The Medical Bureau of the Columbian Exhibition has been organized in Chicago, under the medical directorship of Dr. J. E. Owens, assisted by Drs. Allport, Yeager, and Plummer. A temporary dispensary and emergency hospital has been constructed, where medical and surgical attendance and medicines are furnished to employees, of whom there are already over two thousand on the exposition grounds during the day, free of charge. The Bureau is amply equipped with instruments, medicines, operating-room furniture, stretchers, cots, and an orderly. The City Police Department has furnished a patrol wagon for ambulance service, to be used until a permanent ambulance has been constructed, and the Exposition Company provides horses, harness, and driver. The present bureau, operating during the construction period, will be the nucleus of the medical service of the Fair.

There Ought to be a Medical Sheol, says our indignant contemporary, the *Medical Herald*, for those doctors who are so utterly lost to all the instincts of the gentleman, and which are a part and parcel of the very being of a true physician, as to combine with an equally unscrupulous druggist to defraud the patient whose confidence he at the same time desires and seeks to enjoy. One must have "the cheek of a government mule" to be able to look his patient in the face when writing his prescription, knowing that his commission will be added by the druggist.

Dr. William Coggswell, aged seventy-two, died on August 15th, in Bradford, Mass. He was graduated from Dartmouth Medical School, and began the practice of medicine in 1845. He was President of the Massachusetts Medical Society in 1876, and later held prominent positions in numerous societies and associations, both medical and lay.

Yellow Fever in Vera Cruz.—Persons recently arrived in this city from Vera Cruz, Mexico, bring confirmation of the report that yellow fever is prevalent in that city.

Dr. Hume Field, of Dinwiddie County, Va., died at his home on August 16th, aged sixty-two. He was a prominent surgeon in the Confederate Army during the war.

Punished for Betraying a Professional Secret.—A prominent gynecologist in Germany was recently found liable for $1,600 damages, besides being condemned to pay a fine of $100, for having published clinical notes of some of his cases in a gynecological treatise. His fault consisted in publishing the names of his patients in conjunction with the clinical accounts of their cases

The Surgeons as well as other Officers Must be Treated with Respect in the French Army, and breaches of respect on the part of subalterns are severely punished. The Algerian Council of War has recently condemned a soldier to death for having struck on the face the surgeon of his regiment who had refused to place him on the sick list.

A Remedy for Poisoning by Venomous Snakes and Rabid Dogs.—The Berlin correspondent of the *Therapeutic Gazette* says that a remedy for blood poisoning caused by the bites of snakes and rabid dogs has been discovered in Africa, by a Dr. Engels, in the "wild-growing, black, noble palm." Five hundred negroes bitten by poisonous snakes were treated with the extract of the noble palm, and four hundred and eighty-seven were cured in five days. Of sixty-seven farmers and negroes bitten by rabid dogs sixty-five were saved, while two died of weakness. The remedy is injected under the skin, and causes a moderate fever, not exceeding 35.5° C. On the third day the patient is without fever, swelling and inflammation of the affected part have disappeared, and on the fifth, or, latest, on the seventh, day the patient is cured.

A Hospital for Marasmic Children.—The Paris Municipal Council has decided to build a pavilion in connection with the Maternity Hospital for the reception of newborn children who, after the recovery of the mothers, require special attention. Accommodation is to be provided for twenty infants.

Suicide in the Italian Army.—Suicides have been so frequent of late in the Italian army that the Minister of War has called a council for the purpose of discussing the causes of the tendency to self-destruction, and devising remedies if possible. The soldiers who have been called on to express an opinion as to the reasons for the frequency of suicide among their fellows ascribe it to overwork and improper food.

The Prevention of Blindness.—The Maine Legislature has passed a law providing that, "should one or both eyes of an infant become reddened or inflamed at any time within four weeks after its birth it shall be the duty of the midwife, nurse, or person having charge of said infant, to report the condition of the eyes at once to some legally qualified practitioner of medicine of the city, town, or district in which the parents of the child reside."

Dr. Thomas L. Smith died at his home in Brooklyn on the afternoon of August 14th, at the age of ninety-one years. Dr. Smith was born in Orange, N. J., in 1800. He was educated in the Orange Academy, and at the age of seventeen began the study of medicine under Dr. Samuel Hayes, of Newark, afterward coming to New York, where he received his degree from the College of Physicians and Surgeons, in 1822. He was in private practice for a few years, but entered the navy in 1828 with rank of Surgeon's Mate (now called assistant surgeon), where he did active service for fifty years. In 1837 he was promoted to the rank of Surgeon and subsequently made many cruises to Europe, South America, and the East, serving in the intervals of sea duty in the Navy Yard and Naval Hospital at this port. He was married in 1833 but his wife died nine years later. In 1846 he married again and his wife survives him. In 1871 he was retired with the commission of Medical Director with the relative rank of Commodore. Since then he has lived quietly at his home in Brooklyn.

Dr. G. Halsted Boyland, formerly of Baltimore, Md., has recently passed the examinations at the Faculté de Médecine in Paris, and has established himself in practice in that city. His graduation thesis, which took a very high mark, was entitled the "Non-Diabetic Forms of Glycosuria."

The Congress of German Naturalists and Physicians will meet this year, in Halle, on September 21st to 25th.

Germany Wants to be a Druggist.—The proposal that the whole business of preparing and dispensing drugs should be taken over by the State has again been brought before the German Reichstag.

Death of an Unbeliever.—A wealthy lady died recently in the south of France, at the age of eighty-three, so says the *Lyon Médical*, and in her will left to her physician, "in gratitude for his intelligent and devoted care which had enabled her to reach such a ripe old age," everything he would find in her cabinet. When this was opened its only contents were found to be the untouched mixtures, boxes of pills, and other medicaments (still enveloped in paper as they had been sent by the druggist) which had been prescribed for the defunct by her medical attendant during the past ten years.

Foreign Visitors to the Congress.—Sir William MacCormac, Mr. Arthur Dunham, and Mr. Reginald Harrison, of England, who are on their way to this country to attend the Congress in Washington, will, after the close of the session, be for a time the guests of Dr. Lewis A. Sayre, of this city.

Dr. Henry B. Millard, of this city, was elected, on July 21st, foreign corresponding member of the Paris Academy of Medicine. Dr. Millard was chosen from a large number of candidates, receiving forty-two votes out of fifty-one cast. Dr. Costomiris, of Athens, was also elected a corresponding member at the same session.

Dr. John F. S. Gray, a graduate of the College of Physicians and Surgeons, New York, who formerly practised in this city, and subsequently in Paris, Nice, and Geneva, died at St. Clair Springs, Mich., of Bright's disease, on August 18th.

Dr. Edward R. Mayer died in Wilkesbarre, Pa., on August 17th, in his seventy-second year. He was graduated in medicine from the University of Pennsylvania, in 1848, and at the time of his death was one of the oldest practising physicians in Wilkesbarre.

The Treatment of Mad Wolves' Bites.—Owing to the number of rabid wolves in Roumania and the neighboring countries, Professor Babesch, Director of the Bacteriological Institute in Bucharest, and one of the ablest pupils of Pasteur and Koch, has had many opportunities of treating persons bitten by mad wolves by Pasteur's method, unfortunately, however, without success, for the symptoms of the disease broke out much too quickly to admit of an effective cure by the application of lymph taken from the spinal cord of rabbits that had died of hydrophobia. In view of this sad fact, Professor Babesch has for some time past been making experiments with the purpose of ascertaining whether the immunity from the virus of hydrophobia conferred by Pasteur's method cannot be transferred by inoculating the blood of animals thus rendered immune to other warm-blooded animals. These experiments showed that such inoculation had a prophylactic effect, even in cases in which Pasteur's spinal-cord lymph, under otherwise quite identical conditions, produced no such results whatever. Of twenty seven persons on whom the inoculations were made twenty-four recovered.

A Large Fee.—The largest fee I ever got, writes Dr. William W. Parker in the *Virginia Medical Monthly*, was from an Irish girl, eight years old, whose sister, sixteen years old, was lying ill with pneumonia. It was many years ago. She was the daugeter of a poor widow in the suburbs. There were two smaller children in the family. It was by the labor of this sixteen-year-old daughter that the family got bread, and I saw her value to the household. I told the mother my fears, which it seems the eight-year-old child overheard, and dreadful alarm filled her breast. She waited on the sick sister with the greatest tenderness, and the smaller children were kept quiet and orderly. I promised the mother I would call again late at night. It was dark and rainy. Fears and forebodings increased with the surrounding gloom. The eight-year-old girl could not stay in the house, but in spite of the cold remained out-doors watching for my coming. When in the distance she heard the sound of horses' feet, her heart swelled with hope and fear, but when, peering through the darkness, she caught sight of me she exclaimed, with an emphasis and heartfelt earnestness that thrilled me through and through, and which I shall never forget, "Thank God, here comes the doctor!"—a prayer of thanksgiving that went as straight to heaven as that of sainted prophet or priest, and I felt that even my name had been mentioned and honored in the courts of heaven. It may be, too, the prayer of that little orphan girl has turned aside the dart of death uplifted against some dear one of my own household.

An Hydrostatic Stethoscope has been invented by Dr. T. T. Reynolds, surgeon to the steamship City of Paris. It is described and pictured in the *Lancet* of August 1, 1891. In shape it resembles the ordinary wooden stethoscope, but it differs from it in being filled with water, the fluid being kept in position by a rubber membrane at each end. The expanded aural extremity forms a cushion of water which fits accurately to the ear, and the pressure produced by the ear on that cushion of water makes taut the chest end of the instrument, bringing that end in close apposition with the patient's body, thus affording the physician, the inventor claims, a perfect medium of conduction.

The Alvarenga Prize for 1891, of the College of Physicians of Philadelphia, has been awarded to Dr. L. Duncan Bulkley, of New York, for his essay on Syphilis Insontium.

Advice to a Young Physician.—The following letter, written eighty years ago by Dr. Benjamin Rush, applies so well to present conditions and is so full of sound advice that we publish it here:

"PHILADELPHIA, April 21, 1812.

"DEAR SIR: The facility with which a medical education is acquired in our country has multiplied physicians to such a degree that I do not know of a spot in the United States in which you would fix yourself with more advantage than in the one you now occupy. Competition and slow pay are now the conditions of a medical life everywhere. My advice to you is to remain where you are; you will grow with the growth of the settlement. Purchase upon credit, if possible, a small farm; a little debt will make you industrious and furnish you with an excuse to send in your bills as soon as your patients recover. Employ the leisure which a healthy season will give you, in agricultural labors; the more you will obtain in this way the more independent you will be of your patients, and, of course, the more you will be courted by them. Happiness does not consist in wealth. A competence, books, alternate labor and ease, to use the words of the poet Thomson, a good wife, a few friends, vicinity to a church, and conduct regulated by the principles of the Gospel constitute the sum total of all the happiness this world is capable of giving, and these may all be possessed and enjoyed in your present situation.

"From, dear Doctor,

"Yours truly and affectionately,

"BENJ. RUSH.

"TO DR. PETRIKEN."

Gray Nails.—Under the name "canities unguium" Professor Giovanni describes a peculiar affection, characterized by all the nails turning white and opaque. The hair and skin were not affected.

Euphorine, or Phenylurethran is the name of a new anti-rheumatic, antiseptic, and antipyretic, discovered by Sansoni, and recommended by Professor Stiller, of Pesth. Dose, three to six grains.

Dr. du Bois-Reymond, of Berlin, has been awarded a gold medal for his contributions to science.

American Gynecological Society.—The following papers are announced to be read at the coming meeting of this society, in Washington, in September: "The Advantages of Mixed Anæsthesia in Gynecological Surgery," by Dr. John R. Reeve, of Dayton, Ohio; "Concealed Accidental Hemorrhage during Labor," by Dr. Henry C. Coe, of New York; "Diffuse Adenoma of the Uterine Body," by Dr. James R. Chadwick, of Boston; "The Influence of Season on Recurrent Pelvic Inflammations," by Dr. Frank P. Foster, of New York; "The Therapeutic Aspect of Some Ovarian Disorders," by Dr. Edward W. Jenks, of Detroit; "Insanity following Laparotomy," by Dr. J. M. Baldy, of Philadelphia; "Vaginal Hysterectomy by Morcellement; Technique and Indications for Operation," by Dr. Samuel Pozzi, of Paris, France; "A Clinical Study of Primary Carcinomatous and Sarcomatous Neoplasms between the Layers of the Broad Ligament, with Report of Cases," by Dr. Joseph E. Janvrin, of New York; "The Present and Improving Status of Cæsarean Surgery," by Dr. Robert P. Harris, of Philadelphia; "Unique Case of Multiple Neuro-lipomata following Laparotomy," by Dr. H. Marion Sims, of New York; "President's Address," by Dr. A. Reeves Jackson, of Chicago; "The Treatment of Cancer of the Cervix Uteri by High Amputation; Second Series of Cases, with Additional Report on the First Series," by Dr. William H. Baker, of Boston; "The Advantages of Delivery in the Left Lateral Posture," by Dr. Henry J. Garrigues, of New York; "The Influence of Imperfect Development as a Cause of Uterine Disease," by Dr. W. Gill Wylie, of New York; "The Technique of Vaginal Fixation of the Stump in Abdominal Hysterectomy," by Dr. Henry T. Byford, of Chicago; "Can We Avoid Mural Abscesses and Ventral Herniæ after Laparotomy?" by Dr. Horace T. Hanks, of New York; "Some Clinical Testimony as to the Ultimate Results of Removal of the Uterine Appendages," by Dr. Thaddeus A. Reamy, of Cincinnati; "Indications for Abdominal Section in the Treatment of Puerperal Pelvic Inflammations," by Dr. R. B. Maury, Memphis, Tenn.; "A Study Relative to the Functions of the Reproductive Organs in American Indian Women," by Dr. Andrew F. Currier, of New York; "The Immediate Closure of Laceration of the Cervix," by Dr. Cornelius Kollock, of Cheraw, S. C.; "The Conservative Treatment of Pelvic Tumors and Diseases," by Dr. Eugene Gehrung, of St. Louis; "The Anatomical Relations of the Lacerated Perineum to the Mechanics of Its Causation," by Dr. Edward Reynolds, of Boston; "In Memoriam—Dr. Fordyce Barker," by Dr. James R. Chadwick, of Boston; "Ureteritis in the Female," by Dr. Matthew D. Mann, of Buffalo; "The Surgical Treatment of Retroversion and Prolapse of the Uterus, by Dr. Paul F. Mundé, of New York; "A Paper," by Dr. Theophilus Parvin, of Philadelphia; "Series of One Hundred Laparotomies; My Mistakes and Failures," by Dr. A. Palmer Dudley, of New York; "Laparotomy in Trendelenburg's Posture, with Exhibition of a New Operating Table," by Dr. Clement Cleveland, of New York; "The Electrical Treatment of Uterine Fibroids in England," by Dr. George Keith, of Brooklyn; "Diabetes Mellitus Gravidarum," by Dr. Henry D. Fry, of Washington; "A Successful Porro Operation," by Dr R. Stansbury Sutton, of Pittsburg, Pa.; "An Argument against the Stem-pessary or so-called Drain-tube, by Dr. Egbert H. Grandin, of New York.

American Dermatological Association.—The Fifteenth Annual Meeting of the American Dermatological Association will be held at the Shoreham Hotel, Washington, D. C., September 22, 23, 24, and 25, 1891. The following is the programme of papers to be read: Tuesday, September 22d—"Dermatitis Hæmostatica," by Dr. H. G. Klotz; "A Case of Lupus Erythematosus with Fatal Complications," by Dr. W. A. Hardaway; "Report of a Case of Universal Erythema Multiforme, with colored portrait and specimen," by Dr. L. A. Duhring; "An Unusual Case of Sarcoma involving the Skin of the Arm: Amputation: Recovery," by Dr. F. J. Shepherd; "Multiple Sarcomata: History of a Case Showing Modification, and Amelioration of Symptoms with large Doses of Arsenic," by Dr. S. Sherwell. Wednesday, September 23d—Discusson on Tuberculosis of the Skin: 1, "Its Clinical Aspects and Relations," by Dr. J. C. White; 2, "Its Pathology," by Dr. J. T. Bowen; 3, "Its Treatment," by Dr. G. H. Fox; "Thirteen Cases of Tuberculosis of the Skin, with their Treatment," by Dr. J. S. Howe; "A Case of Lichen Scrofulosorum," by Dr. J. Grindon; "Notes of a Visit to the Leper Hospital at San Remo, Italy, with Photographs," by Dr. L. A. Duhring. Thursday, September 24th—"The Treatment of Alopecia Areata," by P. A. Morrow; "A Therapeutic Note on Alopecia Areata," by Dr. L. D. Bulkley; "Morphia Atrophica of Wilson," by Dr. R. W. Taylor; "The Treatment of Pruritus," by Dr. E. B. Bronson; "Prairie Itch," by Dr. L. N. Denslow; "Diseases of the Skin Associated with Derangements of the Nervous System," by Dr. W. T. Corlett; "Treatment of Chronic Ringworm in an Institution for Boys," by Dr. L. A. Duhring. Friday, September 25th—"Notes of a Case of Acute Dermatitis Exfoliativa," by Dr. J. E. Graham; "Note Relative to Pemphigus Vegetans," by Dr. J. N. Hyde; "A Study of Mycosis Fungoides, with Report of a Case," by Drs. H. W. Stelwagon and H. Leffingwell Hatch; "Lymphangioma Circumscriptum, with Report of a Case," by Dr. M. B. Hartzell; "Remarks on Carbuncle, with Report of a Peculiar Case," by Dr. H. G. Klotz; "Note on Erythema et Nævus Nuchæ," by Dr. C. W. Allen; "A Case of Lichen Ruber," by Dr. J. Grindon; "The Personal Equation in Dermatology," by Dr. L. D. Bulkley; "The Hypodermic Use of Hydrargyrum Formamidatum in Syphilis," by Dr. R. B. Morison; "Retarded Hereditary Syphilis," by Dr. R. B. Morison; "Epilation; Its Range of Usefulness as a Dermato-Therapeutic Measure," by Dr. J. Zeisler.

Society Reports.

SECOND CONGRESS FOR THE STUDY OF TUBERCULOSIS.

Held in Paris, July 27, 28, 29, 30, and 31, and August 1, 1891.

(Special Report to the MEDICAL RECORD.)

First Day, Monday, July 27th.

Zinc Chloride Injections.—The members of the Congress were received in the morning at the Hôpital Trousseau, by M. Lannelongue, who exhibited some thirty patients with tubercular arthritis whom he had treated by means of injections of zinc chloride. In each case a plaster cast of the joint, as it was before the treatment was begun, was shown and compared with the actual condition. The oldest case had been under treatment only three months, and none had received over ten injections. yet all showed a marked diminution in the size of the joint, a finer tissue replaced the fungosities, and in some cases there was considerable painless and non-spasmodic joint motion possible. M. Lannelongue then demonstrated his method in a case of sacro-iliac disease accompanied with abscess and caries of the crest of the ilium. The solution employed was of the strength of one per cent., and two drops were injected at each point, the number of insertions varying according to the size of the joint, five or six being made in the case of knee-joint disease.

Inhalation of Creasote Vapor.—A visit was then made to the Hôpital Saint-Antoine, where M. Tapret exhibited the apparatus used by him in the treatment of pulmonary tuberculosis by inhalation of vapor of creasote under pressure. The apparatus consisted of a large bell under which the patients sat, in which there was a pressure of one and a half atmosphere, this being maintained by a special contrivance while yet permitting the constant renewal of the air. The inhalations lasted about four hours, a half hour being taken to raise the pressure to the required point, and the same time to reduce it to that of the surrounding air. The air, as it entered the chamber, passed over vessels containing creasote, and became thus strongly charged with the vapor of this substance. While remaining under the bell the patients usually felt very well, not coughing or expectorating at all, but on coming out they usually felt chilly for a time, and had a mild attack of coughing. The results of this mode of treatment in M. Tapret's hands had been most encouraging. He had never seen any accident, such as hæmoptysis, caused by the treatment.

Opening Session.—At two o'clock in the afternoon, the opening session of the Congress was held in the large amphitheatre of the Faculté de Médecine, the members being called to order by the President of the Congress, M. Villemin. The Honorary Presidents for the United States were Drs. Jacobi and Page. M. Villemin made a short address of welcome, in which he reviewed the work done in regard to the prophylaxis and treatment of tuberculosis in the three years which had elapsed since the previous Congress. He touched upon the hope and disappointment caused by the Koch experiment, and said there was no cause for discouragement in this, but rather for greater hope and renewed effort. Tuberculosis is not a cyclical infectious disease, like pneumonia, and we have no reason to believe that it wears itself out, or that it becomes in time relatively mild, by reason of the attenuation of the specific micro-organism.

Migration in the Treatment of Tuberculosis.—M. VERNEUIL presented a communication upon the influence exerted by a change of residence upon the development, progress, and termination of the different forms of tuberculosis. These migrations he divided into three classes: 1. Moving from the city to the country, urbi-rural emigration. This is often of great service in arresting the progress of the disease, but in order that this benefit may be permanent the patient must make his residence in the country continuous, and if he returns to the city at all, it must be for very brief periods only. 2. Moving from a large city to a smaller one, urbi urban migration. This is often of nearly as great utility as the urbi-rural change. 3. Going from the country to the city, ruri-urban migration, is fatal to great numbers. Every young man with phthisical tendencies living in the country should have it impressed upon him that to remove to the city is almost certain death.

Inoculation with Attenuated Cultures.—M. GRANCHER reported the details of some experiments he had made, with M. Hippolyte Martin, to determine the effects of inoculation with cultures attenuated by age. The authors had not succeeded in conferring an absolute immunity upon any one of the rabbits experimented upon, yet their investigations had demonstrated that there was reason to believe that a certain degree of protection against the tubercular virus was furnished by this same virus when attenuated.

M. PETIT then presented a report of the work accomplished by the first Congress, and the benefits to science that had resulted therefrom.

Second Day, Tuesday, July 28th.

Identity of Human and Animal Tuberculosis.—This was the first question proposed for discussion. M. VIGNAL had made numerous experiments, as a result of which he concluded that the bacilli of animal and of human tuberculosis were not the same.

M. CHAUVEAU had inoculated cattle with human tubercular virus through the digestive tract by means of intravenous injections, and of subcutaneous injections, and was persuaded that there was but one disease, whether affecting men or cattle.

Tuberculosis of Fowls.—MM. STRAUS and GAMALEIA presented a communication upon this subject. There was, they said, an identity of form and of reaction to the aniline stains of the bacilli from human and fowl tuberculosis, yet the two bacilli were entirely different. The human bacillus does not grow at a temperature of 45° C. (113° F.), whereas this temperature is particularly favorable to the development of chicken bacilli. The pathological effects are also different, the dog readily taking human tuberculosis, but being very refractory to that of the fowl. Rodents are receptive to both varieties, but the results of inoculation differ according to the form of virus used, human tuberculosis producing tubercles, while that of fowls caused a peculiar sort of septicæmia.

M. ROGER followed with a paper on the same subject, relating the experiments made by himself and MM. Gilbert and Cadiot. The conclusions of the paper were that the two forms of tuberculosis were in the main distinct, and that human tuberculosis was, as a rule, innocuous to fowls, and fowl tuberculosis was not inimical to mammals; yet there were cases which seemed to show that one of these varieties might, under certain conditions, become transformed into the other.

Communications of similar import were made by MM. Cournont, Dor, Vignal, and others.

Treatment of Cold Abscesses by Iodoform Injection.—M. REDARD read a paper on this subject in which he described the method used by himself. He used oil as a vehicle for the iodoform instead of ether, the latter causing such painful distention. The results obtained were very good.

Injections of Dog's Serum in Tuberculosis.—M. HÉRICOURT related his experiments in this direction which he had been conducting since 1888. In cases of advanced tuberculosis no benefit had followed these injections, but in those of the second stage there was some apparent improvement, although the bacilli did not disappear from the sputum.

M. Semmola was accustomed to give iodoform internally in doses of one-third gramme every two hours, and had lately employed injections of dog's blood (hemocyne). In mild cases he had observed considerable improvement, but had obtained no cures. He liked the method, however, and it possessed the great advantage that it never killed the patient. This little reference to M. Koch was received with vociferous applause.

M. Pinard showed a little girl upon whom he had operated for tubercular ascites, the presence of tubercles in numbers in the peritoneum being found at this time. In a short time the effusion returned, when the speaker employed injections of hemocyne, with the result of causing the disappearance of the fluid. The speaker had also made trial of dog's serum as a prophylactic in cases of children born of tuberculous mothers. He treated thus twenty-one new-born children weighing less than four pounds, and had only four deaths—which was much below the usual mortality of such infants.

Goat's Blood in Tuberculosis.—MM. Bertin and Picq reported the results of the injection of goat's blood in 114 cases, 300 injections being made. In ten cases abscesses resulted, and in about half there was urticaria, but the improvement in the morbid symptoms was evident and real.

M. Bernheim had also made a number of experiments with goat's blood, and was much pleased with the results obtained.

Tuberculosis in Infancy.—M. Landouzy read a paper on this subject in which he maintained that tubercular disease in infants was of much greater frequency than had usually been supposed, his experience being that one-fourth of all the babies dying at the Hôpital Tenon were tuberculous. He attributed this to the use of cow's milk, and in his service he always insisted that the milk used should be boiled.

Hereditary Tuberculosis.—M. Vignal presented a communication in which he held that the disease was rarely, if ever, inherited, but that it was, when occurring in infants, almost always, if not invariably, acquired.

M. Hutinel said that so called hereditary tuberculosis was generally recognized as a fact, but the question to be settled was, whether a child so affected was born tuberculous or only tuberculizable. Of 118 autopsies of children under one year of age, he had found evidences of tuberculosis in but four. After the first year the proportion of tuberculous children increases greatly, for at least thirty per cent. of children of two years have tubercular lesions. As regards mediastinal adenopathies, supposed by many to occur oftentimes without any other sign of tuberculosis, the speaker held that they were always preceded by pulmonary lesion.

Dr. Jacobi, of New York, said that he had made an autopsy once on the body of a fœtus whose viscera were simply packed with tubercles. The case had been reported in America before, but he recalled it now as being of interest in connection with this discussion on inherited tuberculosis.

M. Bernheim said that the tubercle bacillus could gain access to the fœtal tissues only when vascular lesions of the placenta were present, and thus the disease was acquired by infection, and was not, strictly speaking, hereditary. As to the infection of the ovum at the moment of fecundation by tuberculous semen, the speaker thought it hardly possible, despite the instance reported by Baumgarten.

Third Day, Wednesday, July 29th.

The members assembled in the forenoon at the Hôtel Dieu, where M. Verneuil exhibited several cases of Pott's disease and coxitis, in which tuberculous fistulæ and abscesses had been treated successfully by injections of iodoform in ether. The appearance of an abscess leading directly to the diseased structures in cases of tuberculous arthritis was very favorable to this treatment, as it permitted of the direct application of the iodoform to the lesion itself. In the course of his remarks, M. Verneuil said that in the thirty years of his surgical life he had performed resection of the hip for tuberculous coxitis only six times.

The Bacterial and Morbid Associations of Tuberculosis.—M. Babès, of Bucharest, opened the discussion on this question. He had made a number of investigations to ascertain whether all the microbes found in tuberculous lesions after death were there during life, or were the result of cadaveric decomposition, and had come to the conclusion that the pyogenic microbes were present in the lesions during the life of the individual. Sometimes, his experiments had shown him, the presence of these microbes prepared a previously unfruitful soil for the reception of the tubercle bacillus.

M. Hallopeau's investigations had been made in the line of ascertaining whether these pyogenic bacteria were necessary for the production of suppurating tubercular lesions. He concluded that pus might be found in these cases without the intervention of these pyogenic microbes. The suppuration which had been seen to follow injections with Koch's lymph (a sterilized fluid) was another evidence that these micro-organisms were not essential to the production of pus.

A communication from MM. Verneuil and Beretta was presented, referring to the fact that a cold abscess often heals up after active inflammation has been set up by an invasion of pyogenic microbes, and raising the question whether the pus bacteria might not possibly be destructive of the tubercle bacilli.

M. Arloing instanced, as negativing this question, the fact that inoculations with tubercle bacilli taken from centres of active inflammation were very constantly productive of the disease.

A Hybrid Lesion.—M. Leloir exhibited photographs of a tuberculous patient who was attacked with syphilis. He had lesions of the skin resembling lupus, which were considerably modified by antisyphilitic treatment.

The Infection of Dwellings.—M. Olivier reported several cases in which healthy individuals became tuberculous after taking up their residence in apartments previously occupied by tuberculous persons. He thought the contagiousness of tuberculosis, and the great necessity of thorough disinfection of dwellings lately inhabited by the subjects of phthisis, were points upon which too little insistence was placed by physicians and the sanitary authorities.

Influenza and Tuberculosis.—He said that inquiries addressed to various physicians in many parts of the world, had brought out the fact that influenza and tuberculosis were aggravated one by the other. When the grip attacked those already suffering from tuberculosis the original trouble was made much worse; and many cases were reported in which acute phthisis made its appearance after an attack of the influenza.

M. Tapret presented a communication upon the good results obtained in the treatment of tuberculosis of the respiratory organs by means of medicated compressed air. The method employed by him had been demonstrated to the members of the Congress on the first day of the session, at the Hôpital Saint-Antoine.

M. Gimbert said that he and Professor Bouchard had been the first to recommend creasote in the treatment of tuberculosis. He employed it now by subcutaneous injection, in order to avoid derangement of the stomach. MM. Burlureaux, Guerder, and Vigenaud had all used creasoted oil as recommended by M. Gimbert, and had been greatly pleased with the results obtained.

The Nature of Lupus Erythematosus.—MM. Hallopeau and Jeanselme reported the case of a man suffering from typical lupus erythematosus, and at the same time tuberculous adenitis. He died of acute miliary tuberculosis. Microscopical examinations, cultures, and inoculations proved that bacilli were present in the miliary lesions and in the diseased glands, but not in the lu-

pus tissue. Notwithstanding this and similar experiences, the authors believed that lupus erythematosus was a variety of tuberculosis, the virus, however, being in a much more attenuated form than it is in lupus vulgaris.

MM. Leloir and Lespine presented a communication upon certain forms of lupus and the micro-organisms associated therewith.

(To be continued.)

THE BRITISH MEDICAL ASSOCIATION.

Fifty-ninth Annual Meeting, held at Bournemouth, July 28, 29, 30, and 31, 1891.

(From our Special Correspondent.)

SECTION ON SURGERY.

First Day, Wednesday, July 29th.

The President, Mr. J. Ward Cousins, in opening the Section with an address on "Recent Advances in the Treatment of Tubercular Diseases of Joints," said that great advances had been made in our knowledge of the pathology of tubercle in the past fifty years. He traced this advance and its influence on the treatment of external tuberculosis up to the time when Koch's recent discovery seemed at first likely to revolutionize our treatment.

Koch's Method in External Tuberculosis.—Mr. Watson Cheyne then opened the discussion on this subject. He said that he had for some time given up his wards at King's College Hospital, London, to cases of tuberculosis, and referred to the results of his experience, which had been fully recorded at the Medico-Chirurgical Society in April last. Tuberculin was a remarkable substance, but there were grave objections to its use which went far to counterbalance the benefits conferred by it. The specific fever and inflammatory reaction were often so great that patients lost flesh and were markedly pulled down after the first fortnight's treatment, as much so as though they had suffered from one of the acute exanthems for the same space of time. The local inflammation was also a source of danger, especially where the disease manifested itself in internal organs such as the larynx or meninges, where swelling was fraught with peril, and this local inflammation, by rendering tissues more vulnerable, might cause a spread of the disease and predispose to fresh infection. Mr. Cheyne had, however, observed no instance in his own practice either of infection of previously healthy parts or of acute general tuberculosis, as a result of the injections.

Then, although Koch had claimed that the treatment would confer immunity from future attacks, experience had shown that it did not do so, but that in some cases it predisposed to fresh disease, and that as soon as the treatment was discontinued, rapid relapse would happen, so that the patient would be in a worse case than before.

Experiments on guinea-pigs showed that if one of two animals was treated by a course of injections of tuberculin, and afterward both animals were inoculated with tuberculous tissue, the previously inoculated animal would develop more acute tuberculosis and die sooner than the other one.

Koch had admitted that tuberculin contained various substances, but stated that, while only one of these substances was of curative value, the others were innocuous. There was great reason to believe, however, that to some of these secondary substances the objectionable effects of tuberculin were due.

Modifications of Tuberculin.—Dr. W. Hunter, who had been engaged in analyzing Koch's fluid, joined with Mr. Cheyne in a series of clinical tests of the various bodies contained in it. Dr. Hunter found that on adding alcohol to tuberculin, a precipitate was produced consisting of proteids with a little glycerine and some salts. This for distinction he would call A. The filtrate, which might be called C, consisted of salts with a little proteid matter, which last might be further distinguished as C B. Messrs. Cheyne and Hunter had treated cases with the filtrate C, and found that it produced fever without the local reaction which is so marked a result of tuberculin.

In a case of lupus, the temperature reached 104° F. after six hours, falling to normal after a few hours more. Rigors generally accompanied the pyrexia, but there was no nausea or pain. Each time the injection was repeated a rise of temperature occurred, gradually diminishing until at length no fever followed the injection. Instead of the violent local inflammation of tuberculin, the lupus patches showed a gradual scaling and drying up.

It appeared to the observers that C contained the remedial substance, but that it was mixed with some pyrogenic material which was eliminated in the proteid of the filtrate, *i.e.*, C B. Clinical experiments were therefore next made with this. A case of lupus treated by injections of C B healed in three weeks. Twenty milligrammes were given twice a day without producing fever, malaise, or any bad symptom. In a child, the highest temperature reached was 100° F.; sometimes the temperature was subnormal, but ranged in the cases observed between 97.4° F. and 99.4° F.

It appeared probable that the most effective and least objectionable substance was contained in C B, and was an albumose which might be designated B. Dr. Hunter had isolated this by a process described in his paper on the subject in the *British Medical Journal* of July 25th. This substance was found to produce no general reaction or pyrexia, although it produced a local reaction which was followed by a secondary rise of temperature. This (B) was employed in two cases; in one of lupus of the neck, doses of from two to ten milligrammes were employed. The ulcers healed and the patient was much improved. The other case was one of arthrectomy of the hip, in which the injections were employed with good effect to hasten the healing of a sinus. To sum up: all four injections had a remedial action. The filtrate C was satisfactory, but for the fever it produced. The proteid E of the filtrate (C B) was better still, but slow in its effects. The precipitate A had all the bad qualities of tuberculin. The albumose B gave the best results of all. Mr. Cheyne thought that provisionally C or C B should be used in lupus, combined with operative measures, and also in those cases of joint diseases in which the operation wounds do not heal. In genito-urinary tuberculosis, tuberculin was too dangerous, but C B might be used with safety.

There was no reason why we should refrain from removing tubercular tissue by operation, but this should, when possible, be combined with injections of C B.

Dr. William Hunter said that albumose was an intermediate product between albumin and peptone. He adverted to the laborious nature of the investigation that he had undertaken, and regretted that the secrecy observed by Koch had much hampered him in his work. Koch's statements, that there was one active principle in his fluid, and that local inflammation was essential to its curative action, were now seen to be erroneous. It was scarcely likely that tuberculin would confer immunity from future attacks of tubercle, as claimed by Koch, seeing that phthisis itself did not confer such immunity. As large doses are useless to procure immunity, Dr. Hunter thought that smaller ones should be used, and the attempt to render the patient invulnerable abandoned.

Dr. Pringle congratulated Mr. Watson Cheyne and Dr. Hunter on their work, and said that in his opinion they had made the sole advance in our knowledge of the subject since Koch's discovery was announced. In lupus neither local nor general reaction was essential to cure. He had used C and C B on four lupus cases at the Middlesex Hospital, being in ignorance of the nature of the fluid and its expected effects. His experience resembled that of Mr. Watson Cheyne. One case, after thirty-nine injections, had left the hospital cured. This

patient had previously been unsuccessfully treated by tuberculin.

Mr. Keetley said that this question was entering on a new phase. He had meant to read notes of cases treated by him during the past year, which confirmed for the most part Mr. Cheyne's experience, but after the important communication of Messrs. Cheyne and Hunter he concluded not to do so. He used small doses, and in general his results were favorable, but in one case the wound broke down after union had taken place. The patients' general health had improved during treatment, with one exception.

The speaker considered that it was far too early yet to estimate the value of Koch's discovery.

Mr. Jordan Lloyd had used tuberculin in seventeen cases, and was then quite satisfied that it was worthless, and he had ceased to employ it. Koch's fluid was, no doubt, a remarkable one, and most interesting to the man of science, but it was more than disappointing to patients. The improvement was always transient, and the final state of the patient worse than before. It had also no diagnostic value, as it had given no reaction in patients proved to be tuberculous, while in healthy persons he had seen the "characteristic" reaction. In his opinion it was a dangerous poison, and he felt it to be his duty to come there and speak of its disastrous effects. He had had two fatal cases. In one of these, of enlarged glands with slight doubtful chest signs which the physicians considered did not forbid injection, the patient developed acute miliary tuberculosis after three injections of three milligrammes of tuberculin. He would like to hear of good results, but he was sadly disappointed.

Mr. Odell said that he had not intended to speak in this discussion, but as Mr. Jordan Lloyd had expressed a wish to hear of the good results of tuberculin, he would tell of his experience. This came from two cases of advanced joint disease, in one of which amputation of the thigh had been urged but refused by the patient. This patient now walked without crutches. The other case, of disease of the wrist-joint with pulmonary phthisis, was now nearly cured. He had also cured a case of lupus with the fluid. He gave from 5 milligr. to 5 ctgr., and thought that in most cases the injections had been repeated at too short intervals. He believed that the remedy was all that Koch had said it was, but that it was not all that his too zealous disciples proclaimed it to be.

The discussion was continued by Mr. Morton, Dr. McNeil, and the President. The latter said that he had found tuberculin useful combined with operation in lupus, but not of much value in joint disease.

Mr. Watson Cheyne, in reply, said that he did not think Mr. Jordan Lloyd's disparaging remarks were justified, even by his own cases as narrated by him. He was afraid that a cure could not often be looked for, but he deprecated any hasty resolve to discontinue injections because they did not cure. As long as they were palliative or hindered the disease, they should be persisted in, just as non-curative treatment by drugs such as the bromides was persisted in in epilepsy.

Prognosis of Lateral Curvature.—Mr. Golding Bird read a paper on the limits of curability of scoliosis. He said that it was important to be able to answer the questions, "How far is scoliosis curable?" and, "How far is any given case curable?" as our treatment must depend largely on the answers we could give. There were some exceptional cases that defied prognosis, but in most cases an answer could be given. In the rachitic cases, where the disease was due primarily to bone troubles, cure was not to be expected when rotation was obvious. In non-rachitic cases the prognosis would depend on whether or no secondary bone deformity had supervened on the primary ligamentous lesions. These non-rachitic cases were curable in their early stage, and the result of suspension would guide us in making a prognosis. In bad incurable cases subjective symptoms alone could be relieved or mitigated.

Mr. Noble Smith deprecated, as causing irreparable harm, the tendency of so many surgeons to tell parents that their children would "grow out of" this deformity, in the earliest stages, when alone it is curable. He considered that light steel supports were the best. The poroplastic jacket was utterly unsuited to these cases. The surgeon should keep the mechanical treatment in his own hands just as much as he would that of a broken limb.

Treatment of Pott's Disease.—Mr. Nevitt read notes of a case of "Pott's Disease of the Dorsal Spine" occurring in his own daughter, aged seven, and showed an ingenious "hammock ambulance," and a modified go-cart, which he called a pedambulator, in which the patient was able to walk about while still undergoing moderate suspension. Mr. Nevitt also showed the steel support that he had devised for this case.

Mr. Noble Smith said that Mr. Nevitt's apparatus was most ingenious, but that all attempts to walk were unjustifiable pathological experiments. Recumbency was the best treatment. Mr. Watson Cheyne thought that walking should not be allowed, as it prevented physiological rest of the muscles. Extension secured this rest by overcoming tonic spasm, and in paralysis rendered laminectomy generally needless.

Mr. Freer adhered to the use of Sayre's jacket, with which he had got the best results. The President said that he had found extension most useful.

Mr. Nevitt in reply said that the patient was paralyzed in the lower limbs when put into his pedambulator, but was able after three weeks to propel herself unaided. This he considered a sufficient answer to Mr. Noble Smith's objections. He thought that the extension of the spine produced by a badly fitting support had caused the paraplegia. This was the first case of Pott's Disease that had come under his care.

Second Day, Thursday, July 30th.

Relation of Floating Kidney to Hydronephrosis.—Mr. R. Clement Lucas read a paper on this subject. He remarked that probably many of the so-called phantom tumors of twenty years ago, and those tumors which were then ascribed to localized muscular contraction, were probably movable kidneys, which often elude observation, being obvious at one time and at another being beyond the reach of examination. Movable kidneys might be divided into two groups, according to their relation to the peritoneum. When we examined the connections of the kidney with surrounding parts it became matter of wonder not that a floating kidney should sometimes exist, but that it should not be much more common. The kidney had no proper ligaments, it was surrounded by constantly moving parts, and the amount of fat around it and between it and supporting tissues was liable to great variation.

It was a well-observed fact that movable kidney was commonest in women, and that the right organ suffered much oftener than the left. The object of the present paper was to draw attention to the fact that mobility of the kidney most frequently leads to hydronephrosis and destruction of the organ as an excreting apparatus. The speaker then referred to the symptoms caused by the condition which had often been mistaken for biliary colic. He had known melancholia and mania to supervene, but cease on the removal of the offending organ. Hydronephrosis in movable kidney was caused either by twisting of the ureter or by the pressure of the misplaced or enlarged organ on it. Experience had recently forced him to the conclusion that the use of belts, trusses, and such like palliative measures were not enough, that the kidney was doomed unless a radical operation was performed. He would advise operation in all cases of movable kidney. If the secreting structure of the organ was found to be all destroyed the remains of the viscus should be removed; if it were found to be unimpaired or only partially destroyed nephrorraphy should be performed.

Surgery of the Nasal Cavities.—Mr. Walsham then read a paper on the present position of intra-nasal surgery. He said that twenty years ago this branch of surgery had no special literature and was treated as an insignificant part of surgery, but now the literature of the subject was voluminous, and specialists existed who confined their attention entirely to the diseases of the nasal cavities; indeed he knew of one surgeon who was said to restrict his practice entirely to the morbid conditions of the septum narium, and he had heard that this had even proved to be too wide a field, and that a certain portion of the septum only would in future engage this gentleman's sole attention. In the United States, too, there was a rhinological association. The speaker said that some years ago no one could read a paper or produce a specimen at the Pathological Society but some ophthalmologist would start up and inquire as to the condition of the optic disk, so that it became proverbial that, no matter what the morbid condition or its seat, the surgeon must be prepared to say that he had carefully examined the fundus oculi. Nowadays this tender inquiry after the disk appeared likely to be replaced by the question, "Have you looked into the nose?" There was, in his opinion, a tendency to exaggerate the importance of the organ and to ascribe effects to the condition of the nasal cavities that were due to other causes. As to nasal reflexes, the speaker said that they had been described by ardent rhinologists as occurring in almost every organ of the body, with the exception, perhaps, of the spleen. That the histological resemblance between the spleen and the posterior spongy body had escaped the notice of rhinologists was, however, somewhat surprising.

He confessed that he was skeptical as to the existence of these reflexes, and thought that the cases observed were far too few for safe generalizations to be based on them.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 4, 1891.

Alfred L. Loomis, M.D., President, in the Chair.

The Pathology of the Eclampsia and Albuminuria of Pregnancy.—Dr. Richard Van Santvoord read a paper on this subject (see p. 197).

A Single Theory Insufficient.—Dr. H. C. Coe thought it was impossible to reconcile the various phenomena of the albuminuria and eclampsia of pregnancy with a single theory. Looking at the question from the stand-point of the general practitioner, it seemed evident that there must be different forms of albuminuria. While there were some cases of eclampsia and albuminuria which might be explained on the basis of a toxæmia, others disclosed chronic disease of the kidneys which had not been suspected before. He had in mind particularly pyelitis. In one case he found chronic pyelitis caused by pressure on the ureter, and he had seen several other cases due to one cause or another, in two the eclampsia proving fatal. For this reason he felt that the theory of mechanical obstruction could not be entirely set aside.

The Neurotic Theory.—With regard to the character of the patient, he said that the neurotic were most likely to have eclampsia. Young unmarried girls entering the maternity hospital suffered more or less mental distress, were apprehensive, and were more likely to have eclampsia, looking at the subject from the view of a reflex condition, than were other patients. The author had referred to the sudden appearance and disappearance of a large amount of albumin from the urine without apparent cause, and those who had had experience in maternity hospitals must have seen cases in which without warning eclampsia had developed, and then albumin was noticed for the first time. He had been accustomed to place more stress upon some diminution in the amount of urine passed as a warning symptom than on any other. Regarding Dr. Van Santvoord's case, he thought the radiating pains down the groin, etc., made it not improbable that pressure had a good deal to do with it, and asked if pyelitis might not have been present.

Leans toward Osthoof's Theory.—Dr W. T. Lusk recalled the fact that when Braun's theory was propounded years ago, that puerperal convulsions were due to kidney trouble, certain objections were offered, and those objections, he said, had not been answered unto this day. It had not been explained, for instance, why some patients had convulsions whose kidneys were known to be normal. Nor had it been explained why some persons having kidney disease went through pregnancy without having any convulsions. Again, there might be complete suppression of urine, consequently a large amount of urea circulate in the blood, the patient might even die, yet have no convulsions. It seemed to him that Osthoof's theory offered a more satisfactory explanation of all the phenomena than any other. According to this theory, where a convulsion took place in connection with the sudden stoppage of urinary secretion during pregnancy, it was due to reflex influence. First, there was contraction of the uterus, this in one case causing through the sympathetic system contraction of the arterioles in the kidneys and stoppage of urinary secretion; or the stimulus might be conducted directly to the medulla oblongata; or, again, through the vaso-motor centres, cause contraction of the arterioles of the brain and produce anæmia. This theory would explain the cases in which the renal symptoms were prominent and those in which they were not; it would explain the condition of the pulse, the convulsions, and other phenomena. It did not deny the gravity of the suppression of the urinary secretion. But where the kidneys acted freely there was reasonable hope of life. Dr. Lusk added that when convulsions developed, the important thing to do was to empty the uterus. Veratrum, chloral, etc., were only temporary expedients.

Significance of Arterial Tension.—The President said that in his experience with eclampsia and the albuminuria of pregnancy, which had been gained mostly some years ago, one fact had impressed him in particular, namely, that the danger to the patient depended upon the amount of arterial tension. If there were markedly high tension in connection with temporary or permanent presence of albumin in the urine during pregnancy, it seemed to him always an indication of very grave danger. He had noticed that in chronic disease of the kidneys with albuminuria it was patients who had low arterial tension who passed through pregnancy in safety. Now, there were so many other conditions in which high arterial tension was present without evidence of renal disease, that we must look for other conditions than faulty urinary elimination as the cause. It was worthy of remark that in certain people there were conditions which would produce high arterial tension which would not produce it in others. For instance, one man might eat a hearty meal, take with it a stimulant, and experience afterward no arterial tension, while another man partaking of the same meal and same wines would have high arterial tension. Of these two men, continuing in this course, one would have his life cut short, while the former might continue to live to a good age. It was a physiological condition which impressed on one individual the possibility of high arterial tension from a cause which would not produce it in another. It seemed, therefore, that eclampsia could not be explained solely upon the basis of renal disease.

Dr. Van Santvoord reviewed some of the facts in his case in support of the explanation which he had offered, which he thought would hold good even if pyelitis were present in one kidney as he suspected it might be. Regarding high arterial tension, all writers had looked upon it as an important factor in these cases, some ex-

plaining it on the basis of a toxæmia, others on that of reflex influence.

The Academy adjourned until the first Thursday in October.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY — DEATHS OF DR HUNTER SEMPLE AND DR. HENRY BENNET—AN INSURANCE CASE OF MEDICAL INTEREST — THE ARTIFICIAL PRODUCTION OF DENTAL CARIES.

LONDON, August 8, 1891.

THE forthcoming event is the meeting of the International Congress of Hygiene and Demography. This is looked forward to with considerable interest as, although several sanitary congresses have taken place in this country, the present is the first *international* gathering of its kind to meet in England. The International Congress of Hygiene is of quite modern origin—the first of these Congresses having met in Brussels only in 1876. The Congress will open on Monday next, under the presidency of the Prince of Wales, and will last five days. The morning of each day (except Monday) will be devoted to the reading of papers. Those announced are already so numerous that it would appear an impossibility for even half of them to be read. The work of the Congress, however, is to be divided among ten sections. Nine of these are in the division of Hygiene which will therefore obviously take the front place in the Congress.

Two veteran members of the profession have just passed away, viz., Dr. Robert Hunter Semple and Dr. James Henry Bennet. Their united ages amounted to a hundred and fifty years—the former dying in his seventy-sixth, the latter in his seventy-fourth year. Dr. Semple practised for many years as a physician in the Bloomsbury district, where he remained till his death, though it has long ceased to be a medical neighborhood. A son follows him in the profession.

Dr. Bennet's career was in some respects a very singular one. About a quarter of a century ago he practised in London as a physician and devoted his attention specially to gynecology. In this department he speedily attained a large and lucrative practice. Dr. Bennet had a particularly attractive manner with patients and I have heard that it used to be said of him that such were his gifts in this direction that if he were set down in the middle of Salisbury Plain he would find patients waiting to see him next morning. In the midst of his success he was struck down with pulmonary phthisis. He gave up his practice and retired to Mentone, in order that, as he expressed it, he might, like a wounded hare, die in a quiet nook. Instead of dying, however, he regained health and strength and was able to resume practice. Dr. Bennet spent a portion of the year in England but most of his professional work was carried on at Mentone, where he continued to resort every winter and where he ultimately obtained a considerable practice among the winter residents. His later writings were chiefly on climate, of the value of which in suitable cases of pulmonary consumption he was himself such a signal illustration. The growth of the Mediterranean resorts—and especially Mentone—has been largely due to his advocacy. In Dr. Bennet's youth the old notions as to cases of consumption being hopeless were still prevalent, but he lived long enough to see a complete change of front as to this. Within his time, also, the views formerly current as to the climatic treatment of the disease became considerably modified—as witness the rise of Davos and other Alpine resorts. Dr. Bennet retired from practice a few years ago and spent the close of his life at Vintimiglia—a few miles from Mentone.

An insurance case of medical interest has just been decided by the law courts. A man sixty-six years of age, who was insured for the sum of one thousand pounds against death from accident, fell down on the frozen pavement two months before his death. He was severely bruised and had melæna three days afterward. A day later vomiting of coffee-ground matter occurred. He continued to vomit and pass blood for about three weeks after the accident. These symptoms then ceased, but he died from exhaustion eight weeks after the fall. Two medical men certified that death was due to exhaustion from hemorrhage caused by the fall. The patient, however, had suffered for two or three years from gastric symptoms, and malignant disease had been suspected. On a post-mortem examination being made this suspicion was confirmed, for a cancerous growth was found at the pylorus. The insurance company thereupon repudiated their liability, but the widow brought an action against them and the medical men who had given the certificate maintained that the hemorrhage was not due to the cancer but to the fall. This view was endorsed by the jury, who returned a verdict against the company—a verdict which seems especially unfair in view of the fact that it was a condition of insurance with the company in question that the insurer should declare that he was not the subject of any disease, and that he should renew his policy year by year on this condition.

At a recent meeting of the Odontological Society, Mr. Henry Sewill read a paper in which he stated that he had, as the result of experiments, found that the best agent for the artificial production of dental caries was a mixture of bread and saliva.

New Instruments.

CONVENIENT METHOD OF APPLYING THE PLASTER OF-PARIS BANDAGE TO FRACTURES OF THE LEG.[1]

By GEORGE W. KING, M.D.,

HELENA, MON.

FOR some time past I have used the plaster-of-Paris dressing for recent fractures of the leg in preference to other forms of retentive apparatus, and I am sure that those who trust to ordinary splints in these fractures would gladly exchange them for a dressing that could be made to fit the limb perfectly, and could not become disarranged during the absence of the physician. The plaster splint, skilfully applied, fulfils the conditions very well. It affords a firm, even support to the limb, relieving muscular spasm and limiting the amount of swelling to a re-

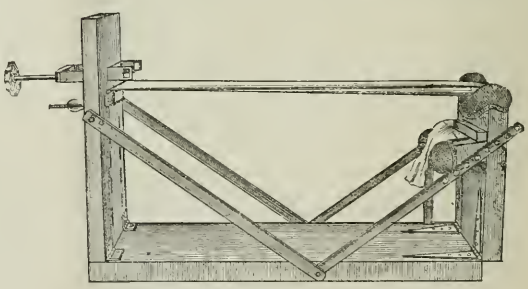

FIG. 1.

[1] Abstract of a paper read before the Montana State Medical Association, May 29, 1891, at Helena, Mon.

markable degree. The principal objection to its use in recent fractures, is the difficulty of maintaining the limb in proper position during the application of the plaster. The tendency of the fragments to slide past each other during

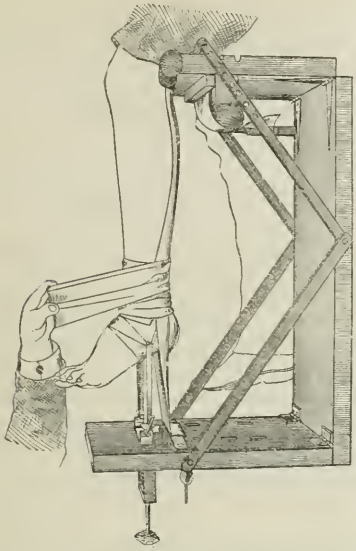

Fig. 2.

the process of bandaging is so great, that it is impossible to prevent overlapping, even by the aid of skilled assistants. Steady, continuous tension, kept on until the plaster hardens, gives the best results.

To facilitate the application of the plaster-of-Paris bandage. I have devised a method of extension and

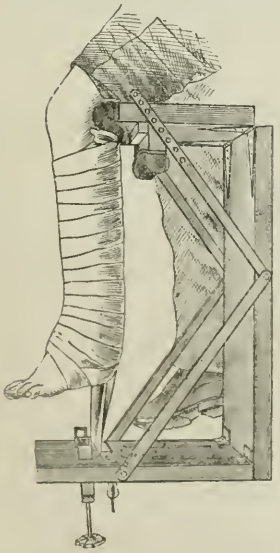

Fig. 3.

counter-extension that has proved a valuable aid. It consists essentially of a framework, over which is drawn a strip of canvas, and upon it the limb rests (Fig. 1). Extension is made by means of a bandage around the ankle, arranged in the form of a clove hitch, the free ends being fastened to the extending bars (Fig. 2). The counter-extension is made by the shorter upright piece of the framework pressing against the under surface of the thigh. The thread of the extension screw is fine enough

Fig. 4.

to make the traction steady, avoiding jerking movement In this position every portion of the limb is accessible ; and there is no need for undue haste, as the patient is

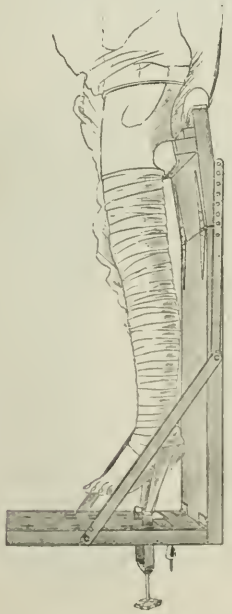

Fig. 5.

comfortable and therefore quiet—conditions most favorable for doing the work well.

To prepare the instrument for use, first cut a slit in the

canvas where the heel rests, to permit a more accurate adaptation of the limb. A piece of sheet wadding should then be placed upon the canvas, and after the limb is in

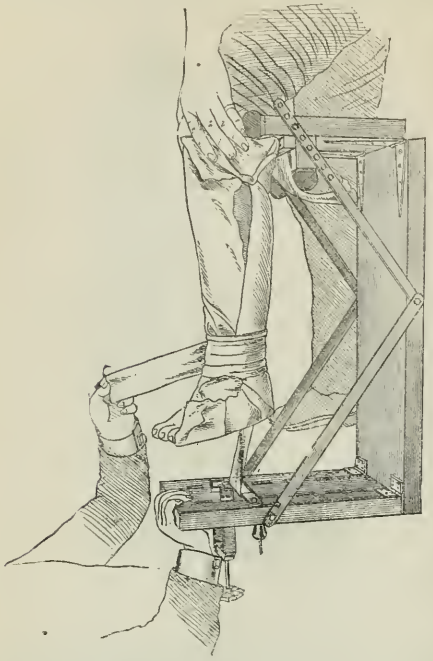

Fig. 6.

position, folded neatly and evenly around it. The plaster-of-Paris bandage can then be applied over all, including the canvas. The latter serves to strengthen the posterior part of the splint. Fig. 3 shows the splint *in situ*.

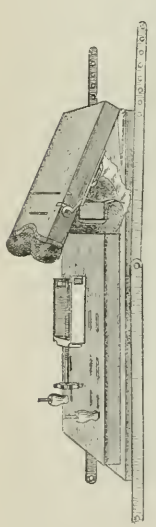

Fig. 7.

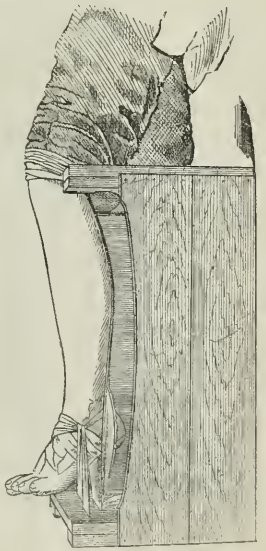

Fig. 8.

When it becomes necessary to carry the splint above the knee, the extension apparatus can readily be arranged for the purpose by lowering one end to a nearly horizontal position (Fig. 4). Figure 5 shows splint applied above the knee.

This form of extension is not limited to the application of the plaster bandage; it is equally available in applying ordinary splints made of wood, leather, or pasteboard (Fig. 6). Fig. 7 shows the machine folded for transportation in a buggy. In the absence of this special apparatus, one can be easily extemporized from a common drygoods box. Fig. 8 illustrates the plan.

I believe the advantages of this method of putting up fractures of the leg will be duly appreciated by all who take the trouble of acquainting themselves with the details necessary to its proper use.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 9, 1891, to August 15, 1891.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor. Granted one month ordinary leave, in extension of sick leave.

GANDY, CHARES M., Assistant Surgeon. Will, upon the final adjournment of the Army Medical Board, resume his leave of absence.

DEWITT, THEODORE F., Assistant Surgeon. Granted sick leave of absence for thirty days.

COCHRAN, JOHN J., Assistant Surgeon. Died at St. Luke's Hospital, New York City, August 5, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 15, 1891.

BAKER, J., Passed Assistant Surgeon. Detached from the Palos and authorized to delay reporting in the United States for six months.

SAYRE, J. S., Passed Assistant Surgeon. Detached from the Ranger and ordered to the Palos.

MEANS, V. C. B., Passed Assistant Surgeon. Ordered to the New York Naval Hospital, September 1st.

THE USE OF COMPRESSED AIR IN CONJUNCTION WITH MEDICINAL SOLUTIONS IN THE TREATMENT OF NERVOUS AND MENTAL AFFECTIONS.

BEING A NEW SYSTEM OF CEREBRO-SPINAL THERAPEUTICS.

BY J. LEONARD CORNING, A.M., M.D.,

NEW YORK,

CONSULTANT IN NERVOUS DISEASES TO ST. FRANCIS HOSPITAL, ST. MARY'S HOSPITAL, THE HACKENSACK HOSPITAL, ETC.

To merely facilitate the introduction of medicinal agents into the system by way of the air-passages, in the form of gases medicated or non-medicated, has heretofore constituted the principal motive among physicians for invoking the aid of compressed air. The experiments of Paul Bert with nitrous oxide and oxygen gas, performed over fourteen years ago, and the more recent proposals of Sée, are illustrations in point.

The objects of which I have been in search are quite different from the foregoing, and have reference not to the introduction of the remedy, but to the enhancement of its effects after exhibition. Let me be more explicit on this point, by stating at once that, in contra-distinction to my predecessors, I shall endeavor to show that, by far the most useful service derivable from compressed air is found in its ability to enhance and perpetuate the effects of soluble remedies (introduced hypodermically, by the mouth, or otherwise) upon the internal organs, and more especially upon the cerebro spinal axis. Some chemical affinity between the remedy employed and the protoplasm of the nerve cell is, of course, assumed to exist; and it is with the enhancement of this affinity—this bond of union between the medicinal solution and the nervous element, that we shall chiefly concern ourselves in the following discussion.

By way of introduction, I may recall the fact that my attention was directed several years since to the advisability of devising some means by the aid of which medicinal substances, and more especially anæsthetics, might be made to localize, intensify, and perpetuate their action upon the peripheral nerves. The simple problem in physiology and mechanics involved in this question I was fortunate enough to solve quite a long time ago; and I must confess that in the retrospect these undertakings in themselves do not seem to me of great magnitude, though in their practical application their significance appears more considerable. Herein lies, it may be, the explanation of the interest which these studies excited in the profession at the time of their publication. These things are, however, a part of medical history; and I merely refer to them at this time because they have led me to resume the solution of a far greater problem—that of intensifying, perpetuating, and (to some extent at least) localizing the effects of remedies upon the brain and spinal cord. I speak of resuming these studies because, as far back as 1880 and 1882, I made some attempts—albeit rather abortive—in the same direction.

In constructing the argument for the following study, I am beholden more especially to three facts, the knowledge of which came to me as the direct result of experimental tests. One may place confidence, therefore, in the procedure which I have based upon these premises, for at no point, I think, in the following argument will mere affirmation be found to have usurped the place of sound induction. Without anticipating further, then, let me specify as briefly as may be the nature of these facts.

Premises of Argument. *First Fact.*—The amount of ether, chloroform, chloral hydrate, the bromides, strychnine, and many other remedies, required to produce physiological effects upon the cerebro-spinal mechanism, may be reduced by first securing a ligature around the central portion of one or several of the limbs of an animal, so as to interrupt both the arterial and venous circulation.

The proof and explanation of this may be thus presented:

In the first place, it is well known that children and small animals are affected by much smaller quantities of anæsthetics and other medicinal substances than are required to produce equal effects in men and large animals.

At first sight, there appears to exist a certain definite relation between the weight of the animal and the quantity of medicament required to produce physiological effects. On closer inquiry, however, we find behind this proposition the deeper truth that the real proportion is between the magnitude of the blood-mass and the amount of medicament. Thus, if we withdraw a considerable amount of blood from a large dog, we may be able to affect him by much smaller doses than those required under ordinary circumstances; and, among human beings, we find the anæmic much more susceptible to remedies than the full-blooded of equal weight.

The degree of saturation of the blood-mass with the remedy is obviously, then, the principal thing; the greater the amount of blood, the more remedy—everything else being equal—we shall have to give in order to obtain definite results.

If we wish to embody the proposition in a mathematical statement, we may do so in the following simple manner:

Let a represent the total quantity of blood, b the amount of remedy exhibited, and x the magnitude of the physiological effect. We shall then have the simple formula, $x = \frac{b}{a}$.

Again, if we withdraw a certain quantity of blood from the circulation by venesection, and call that amount d, we shall then have the formula, $x = \frac{b}{a - d}$. But, if we wish to act upon the organs of the trunk, and more especially upon those contained within the cerebro-spinal canal, it is not necessary to resort to such a drastic expedient as copious blood letting; for, in place of this, we may dam up and effectually eliminate from the rest of the body a certain amount of blood by passing a ligature around the central portion of one or several extremities, so as to interrupt the circulation in both artery and vein. When this has been done it is clear that we may introduce a remedy into the system by way of the stomach, or hypodermically into some portion of the trunk; and it is equally certain that a remedy so introduced will be diluted only in the ratio of the amount of blood freely circulating, and more especially by that contained within the trunk and head. That which is incarcerated behind the ligatures is as effectually withdrawn from the realm of physiological action as though it had been abstracted

by the surgeon's knife. Elimination by the knife and elimination by the ligature are, for present purposes, then, one and the same thing. Hence, if we let d' represent the amount of blood incarcerated behind the ligatures, x the magnitude of the physiological effect which we are seeking, b the amount of remedy exhibited, and a the total amount of blood contained in the whole organism, we shall have the formula, $x = \frac{b}{a - d'}$, $= \frac{b}{a - d'}$.

Several years since, I had an excellent opportunity of proving the truth of the foregoing, in connection with the administration of ether in the case of a patient who resisted all attempts to anæsthetize him in the ordinary way.

The case in question was a man under treatment at the Manhattan Eye and Ear Hospital, upon whom it was deemed advisable to perform an operation. As has been said, the ordinary means of inducing anæsthesia had proven ineffectual, for the man was a confirmed drunkard; and it was at this juncture that I was called in consultation and requested by my friend, Dr. David Webster, one of the surgeons of the hospital, to endeavor to devise some means of getting the man under the influence of the anæsthetic.

The procedure which I suggested was this:[1] Around the upper part of each thigh a flat rubber tourniquet was tightly drawn and secured in place in the usual manner. By this means the sequestration of all the blood contained in the lower limbs was accomplished; but, inasmuch as both artery and vein were compressed, only the amount of blood usually contained in each limb was shut off from the rest of the body—which would not have been the case had we contented ourselves with merely compressing the veins, as some have done. In subsequently commenting on my published report of this case, that most accomplished writer and physician, Henry M. Lyman—than whom there is no greater authority on anæsthesia—observes that the plan proposed and adopted by me on this occasion (that of compressing both vein and artery) is far preferable to compression of the vein alone.

The reason for this is not far to seek. When we compress the veins alone there is a rapid accumulation of blood in the extremities through the accessions derived from the uninterrupted arteries. Now, as this blood is derived from the trunk, and consequently also from the organs contained within the cerebro-spinal canal, there is danger of syncope and even heart-failure. When, on the other hand, both artery and vein are compressed no such derivative action occurs, and all danger is consequently removed. With an apology for this brief digression, I now return to the interesting case which has given rise to it.

Having, as previously stated, applied tourniquets to the central portion of the lower limbs, the ether cap was placed over the mouth and nose of the patient, and in an incredibly short time he was unconscious, and the surgeons were able to go on with the operation.

The late Dr. Cornelius R. Agnew and many other members of the staff of the hospital were present, and gave emphatic expressions of approval.

Dr. F. W. Ring, Assistant Surgeon to the Manhattan Eye and Ear Hospital, declared that both the amount of ether and the time consumed in its administration were infinitesimal when compared with what had been expended in previous efforts at inducing anæsthesia in the usual way. The facts brought out on this occasion, with regard to the administration of ether, have since been repeatedly verified by different observers; so that at the present day their validity cannot be questioned. I will merely add, however, that I have long known that the dosage of phenacetin, antipyrin, morphine, chloralamid, chloral, the bromides, and many other remedies might be reduced by resort to the same procedure; all of which is merely equivalent to stating that their pharmaco-dynamic energy may be increased in this way. And this brings us to the second fact, which requires no special elaboration and may be stated thus:

Second Fact.—The duration of the effect of a remedy upon the cerebro-spinal axis is in the inverse ratio of its volatility; and this is equally true whether the remedy be given with or without the precautions previously detailed. For example, the anæsthetic effects of ether disappear shortly after removal of the inhaler, whether we apply tourniquets to the extremities or not; but, on the other hand, the analgesic influence of antipyrin, phenacetin, morphine, and other like remedies lasts very much longer, and their dose may be reduced, or—what is the same thing — their pharmaco-dynamic potency may be enhanced by the sequestration of the blood contained within the extremities. So far as I know, I was the first to announce this fact. In so far as a simple expression of the above truth is concerned, we may employ the following formula:

Let a represent the normal blood mass contained in the entire body, d' the amount of blood sequestrated by the ligatures, b the amount of the remedy, c the volatility of the remedy, and x the pharmaco-dynamic potency of which we are in search; we shall then have

$$x = \frac{b}{(a - d') \times c}.$$

We now arrive at our third fact, which will require more extensive elaboration.

Third Fact.—The pharmaco-dynamic potency of stimulants, sedatives, analgesics, and probably of all remedies which possess a chemical affinity for nervous matter, is enhanced by exhibiting them (the remedies) in solution or soluble form—hypodermically, by the mouth, or per rectum—while the subject remains in a condensed atmosphere. And, as a corollary, it may be stated that this increase, this enhancement of the potency of the remedy is, within certain limits, in the ratio of the atmospheric condensation.

To express this truth mathematically is not difficult. Thus, when a represents the amount of blood of the whole body, b the amount of the remedy, e the amount of atmospheric compression, and x the pharmaco-dynamic potentiality which we are seeking, we shall then have the simple formula

$$x = \frac{b \times e}{a}.$$

A definite conception of the truth of this proposition will, I think, be more readily attained by the presentation of the steps which led me to its discovery.

Let me begin, then, by stating that my attention was attracted several years ago by that unique complex of symptoms known as the "caisson or tunnel disease." As most physicians are aware, the caisson disease is an affection of the spinal cord, due to a sudden transition from a relatively high atmospheric pressure to one much lower. Hence, those who work in caissons, or submerged tunnels, under an external pressure of two atmospheres or even more, are liable to be attacked by the disease shortly after leaving the tunnel. The seizure never, however, occurs while the subject is in the caisson, or in other words, while he remains under pressure. Moreover, when the transition from the condensed atmosphere to that of ordinary density is gradually accomplished, which may be done by letting the air escape from the lock very slowly, the caisson disease is rarely if ever set up. It is the systematic disregard of this principle by those who work in compressed air that is responsible, or largely responsible, for the occurrence of the disease.

The chief clinical features of the caisson disease are pain, which may be relatively mild, as when confined to a circumscribed area of one extremity, or of frightful intensity, as when it appears in the ears, knees, back, or abdomen; anæsthesia and paralysis, usually of paraplegic

[1] On the Effective and Rapid Induction of General Anæsthesia, The New York Medical Journal, October 22, and December 24, 1887.

type; bladder symptoms, assuming the form of retention or incontinence; and, more rarely, rectal disturbances (usually incontinence).

These phenomena, or rather some of them, appear some time within half an hour after the subject has left the compressed atmosphere. It was while investigating this most interesting affection as it occurred in the course of the construction of the Hudson River tunnel, that I was able, at the same time, to study the effects of compressed air upon the organism, and especially upon the nervous system, as exhibited in a large number of persons.

The results of these studies I now submit without hesitation, and in all candor, to the judgment of the profession, believing, as I certainly do, that their practical significance from a neuro-therapeutic stand-point is assured. Without anticipating, however, let me state that the first thing which impressed me about compressed air was its extraordinary effect upon cerebral and cerebro-spinal function.

Those who remain for a certain length of time, not too long, however, in the condensed atmosphere exhibit a most striking exacerbation of mental and physical vigor. They go up and down ladders, lift heavy weights, are more or less exhilarated, and, in short, behave as though under the influence of a stimulant.

Hardly had I observed these things, which are perfectly well known to those who have been able to familiarize themselves with the ordinary effects of compressed air as used in caissons and submarine works of various kinds, when my attention became attracted by what at first appeared to be a phenomenon of trivial importance. In a word, I observed that some of the men exposed to the effects of the compressed air were more exhilarated by it than others. Upon superficial reflection one might have supposed that this discrepancy in physiological effect was to be accounted for merely on the basis of constitutional idiosyncrasy; maturer thought, however, convinced me that the exaggerated effects of the condensed air were both too numerous and too constant to be amenable to such an explanation. This led me to study the habits of the men; and thus it was that I arrived at a discovery of real practical value to neurotherapy. To be brief, I found that a certain percentage of the men, before entering the compressed air employed in the construction of the Hudson River tunnel, were in the habit of drinking a quantity of alcohol, usually in the form of whiskey. So long as these men remained outside the tunnel, where the atmospheric conditions were normal, they were not visibly affected by their potations. When, however, they entered the compressed air of the tunnel, but a short time elapsed before they became exhilarated to an inordinate degree, acting, as one of the foremen graphically expressed it, "as though they owned the town."

On the other hand, when the customary draught of alcohol was withheld from them, these same men were no more, if as much, exhilarated on entering the compressed air as were their fellows.

The effects of alcohol, then, are enhanced by exposing the subject to the influence of an atmosphere condensed to a considerable degree beyond that of the normal atmosphere.

Acting on the hint derived from this discovery, I proceeded to administer absinthe, ether, the wine of coca, vermouth, champagne, and other stimulants, before exposing the subject to the influence of the condensed atmosphere, and invariably observed analogous effects, *i.e.*, palpable augmentation of the physiological effects of the remedy.

Upon what principle does this augmentation of physiological effect depend? how is it to be accounted for?

In my opinion, the answer to this question may be given as follows: In the first place, we know that the primary effect of the compressed air upon the organism must be to force the blood from the surface of the body toward the interior, and especially into the cerebro-spinal canal. Or, to express it more succinctly, the blood will be forced in the direction of the least resistance, that is, into the soft organs enclosed by bony walls, which latter completely shut out the element of counter-pressure. Now, when the blood-stream is freighted with a soluble chemical of some sort—let us say, for the present, with alcohol—this medicated blood will exert its greatest chemical effect where the tension—the pressure—is greatest, that is, in the cerebro-spinal canal. The reason for this is found in the fact that endosmosis is most pronounced where the blood-pressure is greatest. This explanation of why the effects of alcohol are enhanced by exposing the individual who has taken it to the effects of a condensed atmosphere will, I believe, appeal to the physiological conceptions of most medical men. It was the above course of reasoning which, at this stage of the argument, led me to the idea that, just as the effects of stimulating substances are enhanced by exposing the subject to the influence of compressed air, so, inversely, sedatives and analgesics, when brought in solution into the blood-stream either hypodermically or by the stomach, might be greatly enhanced in effect by causing the subject to remain, while under their influence, in a condensed atmosphere.

When I came to investigate the validity of these predictions, as I did shortly after the introduction of antipyrin, phenacetin, and the other members of the same group of compounds, I found my predictions verified, and, indeed, exceeded. To summarize the whole matter, I ascertained that not only could therapeutic effects be obtained from much smaller doses by exposing the subject to the influence of a condensed atmosphere, but, what was of equal interest, I found that the analgesic influence of the remedies was much more permanent, was prolonged, in short, by this mode of administration. When we consider how great must be the nutritive changes in the nervous system, and especially in the cerebro-spinal axis, consequent upon increasing the blood-pressure in this way, I hardly think that these things should be matters of astonishment.

Concerning the Practical Application of the Foregoing Facts.—Truths like the foregoing possess, however, much more than a theoretical interest, and we should be greatly lacking in perspicuity did we not seek to derive from them something further than a foundation for mere speculation. Indeed, the whole tenor of these facts is opposed to such a course, for, view them as we may, the thought inevitably arises, that here are things which contain the germ of some practical acquisition. This, at least, is the impression which they engendered in my own mind—an impression, which, being unable to rid myself of, I have allowed to fructify. Nor has regret followed this tenacity of purpose, since, by the *combination* of the three principles previously enunciated, I have been able to devise a procedure which, in my hands, has yielded flattering results in the treatment of a wide range of nervous affections, and notably so in melancholia, chorea, insomnia, neurasthenia, and painful conditions of various kinds.

Recapitulation of Argument.—The method in question consists, then, in the combination of the three facts already elucidated. To recapitulate, they are:

1. That the effects of remedies upon the cerebro-spinal axis may be enhanced by the sequestration of the blood contained in one or more extremities, previous to the administration of the medicament. This is only another way of saying that the quantity of a remedy required to produce a given physiological effect, may be reduced by any expedient which suspends, or sequestrates, the blood in one or more extremities. As has been previously said, however, care should be exercised to avoid dangerous exsanguination of the trunk, and consequently of the respiratory and cardiac centres contained in the medulla. This may be done by compressing the central portion of both artery and vein; but I shall presently indicate a better way of accomplishing the same thing.

2. The duration of the effect of a remedy upon the cerebro spinal axis is in the inverse ratio of its volatility.

For this reason the anæsthetic effects of ether disappear shortly after removal of the inhaler, whereas solutions of antipyrin, phenacetin, morphine, and other salts possessing an affinity for nervous tissue exert much more permanent effects upon the cerebro-spinal system.

It is evident, therefore, that the administration of

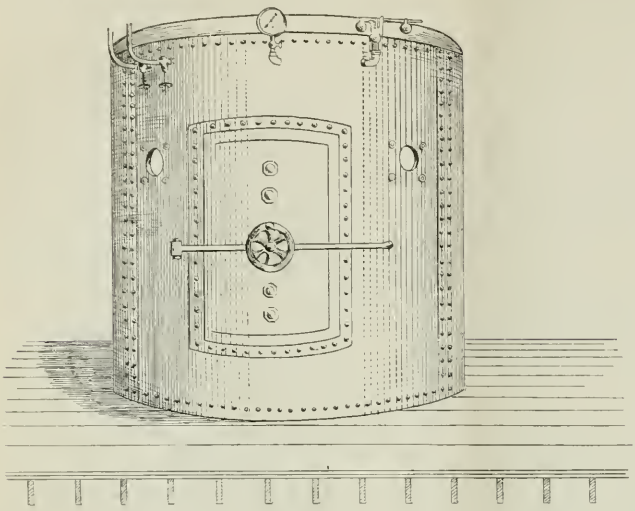

Fig. 1

remedies designed to exert an influence upon the central nervous system in the form of gases, must be far inferior to the exhibition of potent solutions hypodermically or by the mouth.

3. The pharmaco-dynamic potency of stimulants, sedatives, analgesics, and probably of all remedies possessing a chemical affinity for nervous matter, is enhanced by exhibiting them (the remedies) in solution, or at least in *soluble form while the subject remains in a condensed atmosphere.*

And, as a corollary to this, it may be stated that this increase—this enhancement of therapeutic effect is, within physiological limits, in the ratio of the atmospheric condensation. By physiological limits we mean simply that there is a degree of atmospheric condensation beyond which we cannot go without jeopardizing the well-being of the subject.

I think enough has now been said to exhibit in a striking manner the advantages of a therapeutic kind which would inevitably attend the embodiment of these fundamental facts in one comprehensive system. Such a combination I have succeeded in bringing about in the following way.

The Author's System of Using Compressed Air in Conjunction with Medicinal Solutions in the Treatment of Cerebro-Spinal Affections.—In the first place, I have had constructed a large metal chamber, capable of hermetical closure, and able to withstand a pressure equal to that of a locomotive boiler (Fig. 1). This chamber is cylindrical; it is six feet in diameter, six and one half feet high, and its walls are composed of soft steel. The ends of the cylinder, which compose the top and bottom of the chamber, are five-eighths of an inch in thickness, while the cylindrical walls are somewhat less heavily constructed. The seams are not secured by rivets but by bolts, so that the chamber was brought into my house in sections and erected in one of the consulting-rooms without noise or other disturbance.

Access to this chamber is afforded by a massive door, swung from the centre upon ponderous hinges, which peculiar arrangement admits of a very exact coaptation of the door to its frame. The edges of the latter are of course armed with a thick roll of india-rubber. To further insure a hermetical closure an adjustable cross-lever has been provided, so that a screw acting by the aid of a hinge from the centre of the door upon this lever or cross-bar enables one to draw the door—which opens inwardly—firmly against its frame.

The ingress and egress of the air, which is derived from a pump actuated by an electric motor of one horse-power, are regulated by adjustable valves. By this arrangement it is possible to accurately regulate the amount of air-pressure deemed applicable in a given case. In addition to these appliances a safety-valve and pressure indicator have also been provided. The amount of pressure commonly employed is, however, vastly below the maximum point of endurance of the chamber, which, on account of its unusually solid construction, is capable of withstanding enormous strains. How great is this strength may be gleaned from the fact that, in its completed condition, it weighs over two tons. I feel that great credit is due to the Cockburn Barrow & Machine Co., of Jersey City, for the conscientious manner in which they have performed this portion of the work. As is well known

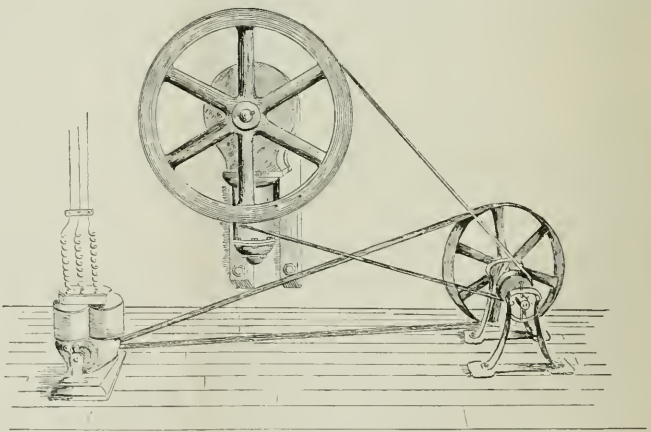

Fig. 2.

to the engineering fraternity, this firm has had an extensive experience in the use of compressed air in caisson and tunnel work, notably in the case of the Hudson River tunnel and the foundation work of the Hatteras lighthouse. It gives me pleasure to acknowledge my special indebtedness to Mr. William C. Barr and Mr. D. B. S. Cockburn, both of whom have been assiduous in their endeavors to render the mechanical details all that they should be.

I cannot leave this portion of the subject without indi-

cating briefly the principal features of the mechanism employed in condensing the atmosphere within the chamber. For this purpose I have had placed in the cellar of my house a one horse-power electric motor, actuated by the current derived from the street conduits of the Edison Electric Illuminating Company. To the motor is joined, by appropriate belts and counter-shafting, an air pump (Fig. 2) of superior construction, and with a capacity of more than 140 strokes to the minute, the length of each stroke being six inches, and the diameter of the cylinder of the pump being also six inches.

By the aid of a system of wires, switches, and a resistance-box one is able to start this mechanism from the floor above, in the immediate vicinity of the air-chamber, without the slightest danger of causing a derangement of the belts and pulleys employed in joining the pump and motor together.

A strong tube of iron conducts the air from the pump through an aperture in the floor to the metal chamber; while a similar tube conducts the redundant air from the automatic exhaust-valve previously described. It is possible in this way to obtain pressures of from fifteen to thirty pounds in a few minutes.

It gives me pleasure to express my indebtedness to Mr. Hadley, of the Edison Electric Illuminating Company, who has superintended this elaborate installation with much diligence and skill.

Let me now describe, in as few words as possible, the manner in which I am accustomed to employ this apparatus in conjunction with medicinal solutions, for the purpose of increasing their pharmaco-dynamic effects, more especially as related to the cerebro-spinal functions.

As stated at the beginning of the argument, I esteem it of advantage, before introducing the remedy into the system, to sequestrate a certain amount of blood in one or more of the extremities. This may be done by passing a ligature around the limb so as to arrest the circulation in both artery and vein; or the ligature may be drawn only sufficiently tight to check the circulation in the cutaneous veins alone. While in the latter case the ligature is much better borne than in the former, so that it may be worn for protracted periods without inconvenience, it possesses the inconvenience that it causes an abnormal accumulation of blood in the extremity, with consequent inordinate exsanguination of the trunk and hence of the spinal cord and brain. To avoid this depleting influence, however, it is only necessary to have the patient apply a moderately tight bandage in the form of an elastic stocking or sleeve (when the ligatures are applied to the arms) before adjusting the ligature (Fig. 3). In this way stasis of the blood circulating in the veins may be obtained without depleting to any considerable extent the brain or cord, and without special inconvenience to the patient, provided that the elastic stocking or bandage has been applied in such a way as not to compress the veins, but merely to limit their expansion. This point I hope to have made sufficiently intelligible. The ligatures having been applied and the medicinal solution administered, either by the mouth, rectum, or hypodermically, the patient enters the pneumatic chamber, the air-pump is set in motion, and by degrees the condensation of the atmosphere progresses until the desired pressure is obtained. When this point is reached the redundant air passes off through the blow-off valve, which, as previously mentioned, is automatic in its action and readily adjustable to any desired pressure.

I have rarely deemed it necessary to employ greater pressure than thirty pounds to the square inch (two atmospheres), and I often employ lower ones, especially when the delicate state of the patient's health seem to demand such a course. How long should the patient remain in the condensed atmosphere? This question cannot be answered dogmatically; as a rule, however, an hour will be sufficient to insure an active therapeutic effect. Exceptionally, however, I have allowed the patient to remain in the air-chamber for two hours or more.

And now let me add a few injunctions respecting the precautions to be observed in connection with the removal of the patient from the air-chamber into the normal atmosphere. In the first place, it is of the utmost importance that this transition from an atmosphere of high to one of relatively low tension should be gradually accomplished. To this end the air should be allowed to escape very gradually, so that from fifteen to twenty minutes are consumed in the operation of reducing the pressure in the chamber to that of the external atmosphere.

While this reduction of pressure is in progress the tourniquet or strap employed in compressing the vessels is removed by the patient, but the elastic stocking or compress is allowed to remain. At the same time the subject swallows fifty or sixty drops of the aromatic spirits of ammonia to which caffeine, the sulphate of sparteine, or some other heart-tonic may be added, at the discretion of the physician. This cardiac stimulant stands properly prepared upon a table in the air-chamber, and the patient is instructed beforehand when and how to take it. The combined effect of the elastic compress and the cardiac tonic is to increase the vaso-motor pressure in the cerebro-spinal

Fig. 3.

system of vessels at the very moment when the compressed air is ceasing to perform that function. As a result of these precautions, I have yet to meet with a single untoward effect from this system of treatment.

Finally, the ventilation in the air-chamber should be carefully looked to, so as to avoid the inordinate accumulation of carbonic acid gas in the chamber and hence in the system; for when the system, and more especially the cerebro-spinal system, is overloaded with carbonic acid, grave disturbances of function may be induced, which manifest themselves after the subject leaves the compressed atmosphere. It is ignorance or disregard of this fact in connection with submarine work which has, I believe, given rise to many cases of severe caisson disease.

In the elaborate and roomy apparatus which I employ there is fortunately no danger of this or any other kind of accident, since the circulation of air is continuous and the pressure capable of exact and automatic regulation.

The next question which naturally suggests itself is, "What are the remedies most suitable to be administered under pressure where a direct action upon the nervous system, and especially the cerebro-spinal system, is sought after? This question has already been briefly referred to at the beginning of this paper, but I should like to answer it somewhat more explicitly. In the first place, all chemicals which possess an affinity for nervous matter, as revealed by their ability to modify the functions of the central and peripheral nervous system, more especially the former, may be given with advantage

while the subject remains in a condensed atmosphere. When I say that such substances may be given with advantage in this way, I mean that the intensity and permanency of their effects may be thus enhanced; or, in other words, they may be given with equal if not greater effect in much smaller doses, and the benefit derived lasts much longer.

A moment's reflection will suffice to convince any thoughtful physician of the significance and magnitude of these things from a practical point of view. It is, indeed, at once apparent that the discovery is capable of a wide application in the treatment of nervous derangements, especially those involving the brain or cord, or both. I have said that the remedies may be given hypodermically, by the mouth, or per rectum. I may add, however, that their exhibition by the mouth dissolved in some diffusible stimulant of an alcoholic nature is to be commended.

Illustrative Cases.—A brief synopsis of a few of the cases in which I have resorted to this system of treatment will best serve to give an idea of its effectiveness and wide applicability.

Case I *Pain Due to Morbid Irritability of the Cord —Spinal Irritation.*—Miss C——, aged forty-five. Had been treated by a number of physicians for obstinate dorsal and intercostal pain. The cautery, galvanism, and all the usual drugs, including strychnine, had been tried without avail. She was brought to my consulting-room by one of my former patients, whom I had been fortunate enough to cure of obstinate headaches.

On physical examination, I found the spine tender on pressure in the cervical, dorsal, and lumbar regions; while such paræsthesiæ as tingling, numbness, and "burning" pains were promptly evoked when she attempted to walk or bend the trunk forward or laterally.

These symptoms had manifested themselves more or less constantly for the past three years; but there was no evidence of any organic alteration involving the nervous system. The pulse was somewhat sluggish, but the heart and lungs and the kidneys were healthy.

While the interview was still in progress she complained of feeling a great deal of pain, and wishing, if possible, to afford her some relief, I gave her twenty grains of antipyrin in a teaspoonful of the aromatic spirits of ammonia, well diluted with water. Although she was somewhat anæmic, there was no unpleasant symptom; but, unfortunately, neither was there the slightest relief, the pain persisting as energetically as before.

On the following morning she was again brought to my office in a carriage. Learning that she still suffered from the painful paroxysm of the day before, I gave her ten grains of antipyrin in a little alcohol, applied two ligatures above the knees, and then installed her upon a comfortable couch within the air chamber. During the first fifteen minutes the pressure reached eight or ten pounds to the square inch. Subsequently it was increased to twenty-five pounds, which point it was not allowed to pass, the blow-off valve being adjusted to that purpose. After remaining in the condensed atmosphere for three-quarters of an hour, the pressure was gradually reduced; and fifteen minutes later, the equilibrium between the air in the chamber and the external atmosphere being established, she rose from the couch and passed through the open door without assistance. She then stated to me in the most positive manner that, not only was she now quite free from all discomfort, but that she had been quite relieved of pain after the first fifteen or twenty minutes of her sojourn in the condensed atmosphere.

There being no considerable return of pain the following day, treatment was continued as before, except that one-twentieth grain of the sulphate of strychnine was given hypodermically instead of the antipyrin before entering the condensed atmosphere. She was also placed upon the albuminate of iron and quinine, both of which she took for some time after the principal meal.

At the end of three weeks, there being no return of pain, she was allowed to discontinue treatment. Quite a long time has elapsed since then, but she writes me that she is quite well, and has gained considerably in weight.

Case II. *A Case of Nervous Headache Promptly Relieved.*—This case is cited merely to show how promptly a distressing phase of headache may be relieved by this plan of treatment, with a minimum of drugging.

Mrs. D. E——, a married lady of forty years of age, has suffered from severe attacks of headache of a "nervous" type for many years. As a rule, the paroxysm begins with more or less visual disturbance, the sight becoming clouded; and all attempts to use the eyes are followed by marked feelings of discomfort in the eyes and head. Nevertheless, there are no tangible ocular defects; the pain is not located in the eyeballs, but is ambulatory, predominating at times in the occipital region, at others in the forehead. The circulatory disturbances are inconsiderable, and do not merit special attention, either from an etiological or therapeutic point of view.

Although all the usual remedies have been tried, she has, until within the past six months, derived the greatest benefit from the use of the bromides. For some time, however, these have failed to abort the attacks of pain, so that she now refuses to further continue their use.

By dint of some persuasion, I finally induced her to take something less than her usual dose of the bromide of potassium, the constricting ligatures being first placed above the knee and elbow, and the elastic stockings being just tight enough to prevent inordinate distention of the vessels. In this way a very complete stasis of the circulation in the superficial veins of all four extremities was obtained; so that the amount of blood sequestrated, and hence uncontaminated by the drug, must have been considerable. On the other hand, the elastic stockings served to prevent any considerable exsanguination of the cerebro-spinal axis or the trunk as a whole, as was shown by the carotid pulse remaining unaltered.

Twenty minutes after taking the remedy, the patient declared that she was no better. She was then placed in the air-chamber, and the pressure increased to fifteen pounds to the square inch, at which point it was maintained for nearly half an hour. The pressure was then gradually reduced, as she intimated that the pain had entirely left her.

Case III. *A Case Showing that the Effects of Alcohol may be Greatly Enhanced by Exposing the Subject in a Condensed Atmosphere.*—R. E. A——, a young unmarried man, has been addicted to the habitual abuse of alcohol for many years. He states that at the present time he is obliged to take double the quantity which he formerly drank in order to obtain the slightest stimulating effect. I had him indicate on a tumbler his usual dose; and, as there exhibited, it could not have been less than two ounces, his tipple being whiskey or brandy. Wishing to ascertain whether in so old an habitué, the compressed air might be invoked as an aid to decreasing the amount of alcohol taken at one time, I gave him half his accustomed dose of whiskey, and had him enter the air-chamber (without ligatures or elastic stockings). The pressure was then gradually increased to eighteen pounds to the square inch, and at this point it was maintained for twenty minutes, the air being renewed from time to time to insure a plentiful supply of oxygen. It was then gradually decreased till the pressure within the chamber equalled that of the external atmosphere. The door was now opened, the patient having been exposed to the influence of the condensed atmosphere for forty-five minutes, and to a maximum pressure of eighteen pounds for twenty minutes. He then stated that he was certain that the degree of exhilaration experienced was quite equal, if not superior, in degree to that usually derived from twice or even thrice the quantity of alcohol.

The capital significance of such an observation as the foregoing will, I am sure, impress itself upon every thoughtful practitioner.

Case IV. *A Case Showing the Beneficial Influence of this System of Treatment in Simple Melancholia (without Delusions).*—A. S. E——, young girl, aged eighteen, has

suffered for the past few months from hysterical attacks, followed by periods of marked depression. She has neither hallucinations nor delusions, but she is irritable and obstinate, and at times difficult to control. Of late she has lost considerable flesh, her bowels are constipated, and, in fact, her whole physical condition is far from satisfactory.

Recognizing the paramount necessity of improving the general bodily state, I have had her drink warm milk—often as much as ten or twelve tumblers a day; I have given her, in addition, both cathartics and diuretics; and I have sought to have her take more air and exercise, at the same time endeavoring to promote sleep by the conservative exhibition of soporifics.

These things have already begun to do good; but, while she is more tractable and less inclined to cause worry to those about her, her attacks of depression, though perhaps not as frequent, are quite as severe as formerly. While suffering from one of these attacks of depression she was recently brought to my office by her mother; and, at my suggestion, she was placed in the air-chamber, a small dose of the extract of absinthe and brandy having previously been given her.

In a short time the pressure was shown by the indicator to be fifteen pounds, and at this point it was maintained for twenty minutes or more. After the lapse of this period, a marked change took place in the patient's appearance, as could readily be ascertained by looking through one of the large glass port-holes. Her face, which had previously worn a dejected, indifferent appearance, now displayed a contented and even happy expression, and she occupied herself with reading the newspaper—something that she had not done before for weeks.

On leaving the air-chamber this air of contentment remained and, according to her mother's statement, she showed no further evidences of depression for the next three days.

Though I had employed the above remedies, and various others as well (without the compressed air), on former occasions and in larger doses, it had never been my good fortune to obtain any appreciable immediate good from them. I feel, therefore, entirely convinced—more especially as I have since been able to produce the same class of effects on several occasions, both in this and other patients—that the enhanced potency of the drugs was entirely due to the concomitant influence of the compressed air.

Case V. *A Case Showing the Enhancement of the Soporific Powers of Hypnotics, and more Especially of Chloralamid by the Administration of the Same, while the Subject Remains in a Highly Condensed Atmosphere.*—E. N——, a neurasthenic woman who has suffered from acute insomnia for several weeks, and who is inappreciably influenced by the usual hypnotics or their combinations, even when given in large doses.

Among other soporifics I have given her chloralamid in doses of forty-five grains, but with quite insignificant success; for in spite of the remedy she declares that she never sleeps more than one hour or two out of the twenty-four. At my suggestion she consented to try the effects of the compressed air treatment.

Accordingly, I gave her a dose of thirty grains of chloralamid—fifteen grains less than she had previously taken at night; and, fifteen or twenty minutes after its administration, the elastic straps having been previously adjusted to the lower extremities above the knees—she entered the air-chamber. The pressure was then raised to fifteen pounds to the square inch, as shown by the gauge; and at this point it was maintained for upward of half an hour, the air being renewed from time to time, but without altering the pressure. While thus exposed to the concomitant influence of the drug and condensed air she became drowsy, and finally fell asleep. From this state of unconsciousness she was only aroused by the noise of the escaping air as I opened the valve of the outlet tube in order to empty the chamber.

On the following day she stated that, at the conclusion of the treatment, she had gone home, and lying down upon the lounge, had immediately fallen asleep, only awaking after the lapse of five or six hours. In other words, she had slept the entire afternoon—something that she was quite unable to accomplish, even previous to the attack of insomnia.

This case is instructive, as exhibiting the continued good effects of this plan of treatment; by which I mean that the soporific tendency persists even after removal of the patient from the condensed atmosphere. I will merely add that this case went on to complete recovery, natural sleep supervening regularly without artificial assistance of any kind after treatment had been continued for four weeks.

Case VI. *A Case Showing that the Soporific Powers of Sulphonal can be neither Enhanced, Accelerated, nor Prolonged by the Concomitant Exposure of the Patient to the Influence of Compressed Air.*—F. I. T——, a Polish Hebrew in middle life, consulted me for insomnia, which he states came on as the sequence of the "grippe." Having adjusted the ligatures about his limbs, I gave him fifteen grains of sulphonal, and half an hour later placed him in the chamber. The air-pressure was then raised to fifteen pounds to the square inch, at which point it was maintained for over an hour. After leaving the air-chamber he stated that at no time had he felt the slightest drowsiness; and moreover, on returning the following day, he declared further that the postponed soporific effects so frequently due to the drug were entirely absent.

Subsequently, I gave him small doses of chloralamid, which were exhibited under a precisely similar degree of pressure (fifteen pounds to the square inch), and with the result that sleep could be induced at pleasure either by day or night. Eventually he recovered completely.

I have cited this case merely to show that sulphonal is not a remedy which is well adapted to be used in conjunction with compressed air.

Case VII. *A Case Showing that the Potency of Diuretics (or at least of some Diuretics) is Enhanced by their Exhibition while the Patient Remains in a Condensed Atmosphere.*—W. E.——, a man of middle age, a sufferer from chronic nephritis. I was consulted with regard to various nervous symptoms, notably irritability and insomnia, from which he had been suffering for several months past, but notably so during the past six weeks.

When I saw him, he had been taking copaiba for some time, and his stomach had become weak and inefficient. In the course of various suggestions pertaining to the management of the neurotic phase of the case, I availed myself of the opportunity thus afforded to recommend that colchicin be substituted for the copaiba capsules.

This was accordingly done, the remedy being exhibited in $\frac{1}{30}$ grain doses. For some reason the quantity of urine excreted was not materially enhanced; and, being informed of this fact, I suggested, merely as a matter of scientific interest, that the remedy be given in conjunction with the compressed air.

He readily consented to this, and I gave him the usual dose of the remedy, and shortly afterward had him enter the air-chamber, where he remained for over an hour at a pressure of eighteen pounds to the square inch. During this time the air was renewed, but without altering the pressure. In the afternoon the same operation was repeated, the patient remaining even a little longer in the air-chamber.

The amount of water excreted during the progress of these observations was collected and measured, with the result that it was found to exceed in quantity that previously passed during the same interval by about one-third.

This observation, though, strictly speaking, without the limits of the subject under consideration, possesses, nevertheless an undoubted collateral interest, inasmuch as it demonstrates that the vaso-motor pressure in the structures

contained within the abdominal cavity is enhanced—though not to the same degree as in the cerebro-spinal cavity—by exposing the subject to the influence of a highly condensed atmosphere.

Corollary to Argument—Final Summary.—The procedure which we have now elucidated with sufficient minuteness, consists, then, of the following elements: 1. Sequestration of the peripheral circulation, especially in the extremities, either by the application of ligatures which compress both arteries and veins, or the arteries alone, or the veins alone. As previously stated, I prefer the latter expedient, provided it be combined with the simultaneous application of an elastic compress (stocking) below the ligature, so as to restrain the expansion of the veins, thus preventing the undue accumulation of blood and consequent exsanguination of the trunk. 2. The introduction of a chemical having an affinity for nervous matter, and especially for that composing the cerebro-spinal axis. 3. The immersion of the subject in air condensed much above the pressure of the normal atmosphere.

We have already considered a variety of effects produced upon the system, and particularly the cerebro-spinal system, by a plan of treatment embodying these three elements. Something has also been said regarding the causation of these phenomena; but the subject is capable, I think, of somewhat further elucidation. I shall therefore bestow a few parting thoughts in giving a more comprehensive answer to the question: Why is it that cerebro-spinal medicaments, when given in this way, are enhanced and, to a certain degree, prolonged in their effects? Or, to state the matter still more concretely, how does it happen that we may give a certain amount of a remedy in the usual way, either by the mouth, rectum, or hypodermically, without visible effect upon the central nervous system, and yet may obtain characteristic effects from that remedy when given in the same dose as before—or even in a smaller one—if we call in the aid of the ligature and compressed air in the manner previously set forth? I shall endeavor to answer this question as succinctly as possible.

In the first place, by applying the ligatures in the manner previously set forth we cause a more or less extensive stasis or sequestration of the peripheral circulation, thus reducing the amount of blood to be impregnated with the medicinal substance. In other words, we have only the blood in the trunk to medicate, while that contained in the limbs—provided we apply the ligature to both arms and legs—remains uncontaminated. Consequently, the dose of medicinal substance, being distributed only throughout the blood-mass contained in the trunk, arrives in a much more concentrated condition in contact with the cerebro-spinal axis than would have been the case had the subdivision extended to the blood contained in the limbs.

To all physiological intents and purposes the size of the individual has been curtailed; and we all know that the smaller animals—other things being equal—are much more susceptible to the influence of medicinal substances, and this is especially true of stimulants and sedatives, than the larger ones. How does the compressed air assist in still further enhancing the physiological effect of the remedy?

To comprehend how this is accomplished it must be borne in mind that the quantity of blood circulating in the trunk is not reduced in volume—or but slightly so—by the application of the ligatures, but is merely shut off, sequestrated as it were, from that contained in the extremities. Consequently, when the condensed air presses upon the blood circulating at the surface of the trunk, it (the blood) is forced in the direction of least resistance, *i.e.*, the cerebro-spinal cavity. Hence the vaso-motor tension will be greatest at this point, and, as a result of this, the transudation of the medicated blood into the tissue of the brain and cord will be greatly enhanced. This, so far as my physiological apprehension serves me a right, is the true explanation of why the effects of a large class of cerebro-spinal remedies are so strikingly enhanced by their exhibition while the subject remains in a condensed atmosphere, with ligatures adjusted to the extremities in the manner previously described. Moreover, in my opinion, the perpetuation of the beneficial effects is due in no small degree to the nutritive changes, which are more or less directly traceable to this increase in vascular tension.

From the facts and considerations already brought forward I think it will be admitted that this system of using compressed air in conjunction with medicinal solutions is capable of extensive application in the treatment of nervous and mental affections, more especially those of functional origin of a rebellious and unyielding type.

For an extensive list of the literature of compressed air the reader is referred to my paper on the "Caisson Disease."*

ONE FORM OF PHARYNGEAL MYCOSIS—MYCOSIS LEPTOTHRICA.

By JAMES E. NEWCOMB, M.D.,

LARYNGOLOGIST TO DEMILT DISPENSARY, ASSISTANT PHYSICIAN ROOSEVELT OUT-PATIENT DEPARTMENT, NEW YORK.

It is often alleged against the results of scientific investigation that they are curious rather than profitable. While this may be to a certain extent true, it is only in accordance with the general rule which obtains with every advance in positive knowledge. Clinical observations accumulate and for a long time remain only speculative. In each instance it remains for some one to bring speculation to a decisive issue and to point out the value of the hitherto merely curious facts. The application of our instruments of precision in the study of the diseases of those portions of the body open to ocular inspection has done much to make medicine approximate to an exact science.

The study of parasitic diseases of the mouth is a notable illustration of what has been said. Our knowledge of their etiology has gradually become more definite and our treatment more exact. Mycosis leptothrica, presenting many points of resemblance in its gross appearance to some of the more common throat diseases, was for a long time overlooked. Closer observation and the aid of staining-fluid and lens have clearly differentiated it from all other affections. This, however, is a comparatively recent event. Consequently, not in text-books but in the journals and clinical reports of the last fifteen years shall we find its literature, and as the years go on it has become a matter of more frequent occurrence, or, let me say, cases are more frequently reported. Our category of irregular forms of throat disease is growing comfortingly less.

The disease, then, is a parasitic affection of the mucous membrane of the mouth, possibly located on any portion thereof. It manifests itself in the shape of white patches of varying size. These are found to contain epithelial cells and various parasitic forms of a vegetable nature, the distinctive ones being the so called leptothrix threads. The local condition may or may not be accompanied by constitutional symptoms. It has been called a benign affection. It is, so far as life is concerned, but, as Heryng [1] observes, this term can hardly with justice be applied to those cases which continue (as some do) from month to month. As to where the process ceases to be a natural accident and becomes a distinct pathological entity (a fact denied by Chiari [2]) it is difficult to say. The tonsillar crypts of healthy persons are at times more or less plugged by these vegetable masses. It is only when the plugs become large enough to entirely fill the crypts and project slightly from the surface that they come under our observation.

Miller [3] gives a very good description of the macrosco-

*Observations on the Caisson or Tunnel Disease, the Medical Record for May 10, 1890.

pic appearance as follows: "It occurs as a dirty-yellowish deposit, varying in size from the head of a pin to a pea, consisting of numerous bacterial forms, and extending deep into the lacunæ of the tonsil. Both or only one of the tonsils may be attacked, while the tongue and soft palate are more rarely affected." According to Schech,[4] the subjective symptoms consist in dryness, tickling, burning, slight pain on swallowing, inclination to hawk, and anorexia. In one case Schech noticed fever, with general discomfort, while weakness and anorexia preceded the appearance of the spots. Miller himself never saw a case with constitutional symptoms.

The history of the disease is not devoid of interest. The older observers seemed to be aware that there was a disease of the throat, the etiology of which was obscure. Mackenzie speaks of an "exudative follicular pharyngitis," Stoerck of "seborrhœa of the follicles of the pharyngeal mucous membrane," Biesadecki of "amyloid degeneration of the mucous glands," based on the iodine reaction to be mentioned later. Rokitansky regarded it as an atheromatous condition, probably of the membrane itself. In 1873 B. Fränkel [5] described it under the title "Mycosis Tonsillaris Leptothrica Benigna," evidently regarding it as a tonsillar affection solely. He asserted that it was an affection hitherto unrecognized, and that it had a definite pathological basis. The first case was accidentally discovered in the course of routine clinical work. The exudations were described by him as punctate, and projecting about one line from the membrane surface. They felt not firm, but rather like mould, and were about the size of an ordinary gland. The epithelium was present around them, and in the secretion removed from the sites there seemed to be small, round bodies in active motion. Upon these preliminary observations of Fränkel our definite knowledge is based.

Concerning the etiology we know nothing positive, any more than do we about the origin of pathogenic germs in general. As early as 1675 micro-organisms were discovered by Leuwenhoek in the human mouth. It is generally admitted that through the propagation of varieties in the Darwinian sense, new species are constantly arising in air and water. They all find ready access to the oral cavity. The disease is not directly transmissible; is not contagious. S. Solis-Cohen.[6] reports a case following rheumatic tonsillitis, diphtheria being then prevalent near the patient's residence. Toeplitz[7] says it may follow diphtheria or any follicular angina, but he does not regard the latter as more liable to be followed by mycotic disease than is any other throat affection. Mouth-breathing was suggested in two cases as bearing on the etiology. In several instances Miller[8] observed it to follow an already existing affection of the pharynx, and concluded that the germ colonizations were made possible by the preceding inflammation. According to this same authority it occurs more frequently in women and children who suffer from enlarged tonsils and are more predisposed to chronic pharyngitis.

As is always the case where attention is directed to a newly discovered or reclassified malady, it does not seem to be so infrequent as was formerly supposed. Yet in the first ten years after Fränkel's paper, in 1873, only some six cases had been reported. In the next four years, according to Goris,[9] only thirty-nine were chronicled. Since that time greater closeness of observation has removed the malady from the category of *rare* to that of merely uncommon affections.

The pathology has been fully discussed by various writers. The gross appearance of the lesion is that of discrete white spots, which may be connected here and there (as I recently saw in one case) by scanty thread-like filaments. The mucous membrane covering the tonsil is the part most frequently invaded, and the left rather than the right in the cases thus far reported. For this latter fact we have no known anatomical or physiological reason, and I am the more inclined to regard it as a mere coincidence which will cease to exist when we may have more voluminous records. The epiglottis, according to Heryng, is more rarely invaded, and the larynx may also suffer; other sites are the glosso-epiglottidean folds (Bayer [9]) and the base of the tongue, especially about the circumvallate papillæ. As to a possible habitat of the leptothrix threads, it is interesting to note that in the so-called "fetid bronchitis" they have been found in the tracheal mucous membrane, in the characteristic fungoid plugs. Leyden and Jaffé [10] have repeatedly found them under these circumstances, and also in the sputa of pulmonary gangrene. In the series of fourteen cases reported by Heryng,[7] the affection was confined to the tonsils in seven. In the remainder the base of the tongue was also affected. Six were men and eight women. The age varies from twelve to sixty-two, the decided preponderance being between twenty-eight and thirty-five (Semon [11]). Seifert [12] has found the exudation on the soft palate. Baginsky, in a case of tracheal ozæna, confirmed the statements of Leyden and Jaffé.

These discrete white spots resemble at times mushrooms in shape, while at others they seem like pointed cones. The bases may be separate, or two or three conical tips may seem to have a common base. They are removed from the membrane with considerable difficulty. Mounted on a glass slide, and teased in a little glycerine previous to examination, there is at once appreciated the fact that the mass seems to be in layers. The outer of these is easily smoothed off, while there is a deeper and harder substratum in the shape of little plaques. A cotton-wrapped probe will often accomplish this brushing off while the mass remains on the membrane. At other times the growth seems more tenacious, and the examining finger experiences a sensation as of feeling rather stiff bristles.

Microscopical examination shows a picture which is at first rather confusing, particularly when one tries to reconcile the various and confusing descriptions that have been given of it. As well described by Vanderpoel,[13] there is a general mass of epithelial cells surrounded by an irregular collection of fungoid spores. Boland,[14] denies the existence of distinct epithelial cells, and regards the masses as "epithelial plates," whatever that may be. These spores are arranged in link-like processes, their ends being rounded, or club-shaped. These link-like processes vary in length, and in some cases curl up at their ends into fine hair-like filaments. Others are like rods, colorless, but with sharp dark borders, the centres seeming to be full of granular matter. Besides these spores there are round or oval highly refractive bodies with dark borders arranged in colonies, or placed separately between the branching spores. The whole goes to make up a network formation, composed of spores and refractive granules. Staining with methyl blue brings out colored and uncolored portions on the stem of the spores. The colored portion is supposed by some to be of an amyloid nature, while the uncolored portions are separate partitions. When the same procedure is carried out with Lugol's solution of iodine and potassic iodide for two or three minutes, the portions taking the color give the characteristic starch reaction. Chiari [2] found that the harder and highly refractive bodies gave off a gas in the presence of hydrochloric acid. This picture of the stained thread-like spores is very striking, and when once seen leaves an indelible impression upon the observer.

The symptoms of the affection are generally local. They consist of a varying degree of buccal irritation causing cough, difficulty in swallowing, sometimes reflex laryngeal pain and the sensation as of a foreign body in the throat. At night the latter seems very dry and stiff. All of these symptoms are of course non distinctive. Constitutional symptoms, if present, exist only in a slight degree. E. Fränkel [15] reports a case with painful deglutition and swelling of the submaxillary glands. Schech noted in one instance fever with general discomfort, weakness and anorexia preceding the appearance of the local deposit. On examination the tonsils may be reddened and swollen. Their epithelial coating is frequently thickened by prolif-

eration and the follicles are enlarged. The change is distinctly superficial. Semon [11] records a case in which the uvula and soft palate were greatly congested, the former being also very œdematous. As a rule, however, there is an absence of evidence of local inflammation.

Three conditions exist from which a differential diagnosis must be made. 1, Diphtheria; 2, follicular tonsillitis, and 3, the so-called tonsillar concretions.

From diphtheria the diagnosis is based on the following points: There is a persistent discrete arrangement of the exudate. There is pretty constantly an absence of fever. There is generally an absence of surrounding inflammation. The masses are much harder than pseudomembrane, and the tongue may be involved, which is rarely the case in diphtheria. For the bacteriologist the absence of the Klebs Loeffler bacillus would be convincing evidence.

In follicular tonsillitis we regularly have pretty marked constitutional symptoms, sometimes out of all proportion to the local lesion. The membrane between the follicles is distinctly inflamed. The exudate is easy of removal and is not friable. It may be here observed that the rapid reproduction of the mycotic masses after removal in any manner from the old roots left in the crypts is remarked by all who have studied the subject.

From concretions the diagnosis is sometimes more difficult. It would seem by this time that we ought to have learned pretty clearly what tonsillar concretions are made of, but we find great diversity of statement concerning their composition. We must remember that leptothrix threads are at times found in nearly every mouth, healthy or diseased. They are therefore apt to be mixed up with whatever morbid products come out of the mouth, Prosser James regards concretions as essentially perverted secretions allowed to remain. Mackenzie considers them as perverted secretions shut up in the substance of the gland by closure of the lacunar mouths. Gruening [16] makes the emphatic statement that "all tonsillar concretions are composed of leptothrix masses," and cites the microscopical examination of fifty cases to maintain his view. He found them to consist of packed bundles of straight cylindrical fibres, often containing starch granules embedded in a granular matrix; they frequently contained, also, chalky masses produced from the precipitation of calcium carbonate from the soluble salts of the saliva. This latter process is frequently brought about by non-parasitic algæ. Vanderpoel [13] takes issue with this general statement. He remarks that when the concretions are young they are soft and cheesy; when old, hard and mortar-like. It can be easily imagined that a sluggishly expressed tonsillar secretion would contain a great variety of substances. Hence we are not surprised to find the concretions containing epithelial cells, salts of iron, soda, potash, and calcium, cholesterin, pus-cells, bacteria, mould fungi, chalky flakes, and even leptothrix threads, but we cannot admit that the latter form the main ingredient. These nondescript masses may be coughed up from time to time, or by irritation of surrounding structures produce abscesses which discharge their own exciting cause. They are not mycotic deposits. If expressed they are very slow in reforming. The mycotic patches always reform very quickly after removal, on exactly the same sites.

There is a unanimity of opinion concerning the indication for treatment. It is to destroy the root of the mycotic bush. Various germicide applications have proven valueless. Though with no great tendency to spread, the spots are very tenacious of life, and if removed by mechanical means leave enough of themselves behind to insure a speedy reproduction. Semon claims to have cured his case with chlorate of potash gargle and troches of tannic acid. Seifert caused such a quick cure with ice and a gargle of borax that doubt has been expressed as to the correctness of his diagnosis. Alum and sulphur are useless. Silver nitrate in pencil answered well in two cases which were especially tolerant to its use, but a relapse occurred six weeks later. Smoking is said to have cured one case (?). Jacobson [17] recommends a bichloride gargle —1 to 2,000. Toeplitz found ferric chloride useless, and others have had a similar experience with other iron salts. Carbolic acid has produced negative results. Chiari applied bichloride solution—1 to 1,000—to the membrane, and ordered a gargle of 1 to 10,000. In one of his cases there were recurrences at stated intervals, the disease often remaining several weeks at each visit. A fact to be borne in mind is stated by Miller, viz., that the deposits usually disappear in a few weeks of their own accord, or as soon as the conditions which make their formation possible are removed. This is rather a sweeping statement, and it seems to me that "sometimes," rather than "usually," is the word here to be used. I have seen one case in which the trouble had persisted fully two months without the least abatement. All of the above agents have proved unreliable, to say the least, and nearly all of them useless. Fused chromic acid has given better results, and the point of the galvano-cautery repeatedly thrust into the root of the growth has answered best of all. In fact, in only one of the reported cases is it distinctly said that the cautery failed to produce a cure. It is easy to see why superficial applications like gargles are useless. At the best they can only affect the top of the growth, while its base remains firmly embedded in the tonsillar crypt. Nay, more, the forcible rubbing on of solutions may abrade the epithelium and so promote the spread of the disease. In the cautery we have an agent going down to the root, and definitely localized in its action. It is, under the circumstances, our ideal therapeutic resource, though several applications may be necessary to effect a radical cure.

Note.—The history of a case recently under my own observation is as follows: Female, aged twenty-eight; single; American; recently nurse in a gynecological ward. Mother was rheumatic and patient herself had had one attack from which she made a complete recovery; measles six years before, but no scarlatina or diphtheria. She had had a few previous sore-throats, but only after taking cold, and they were always trivial. She had never had any previous attack similar to the present.

Two months before coming under observation she noticed that both tonsils were covered with white patches which were persistent. She had no constitutional symptoms and her general condition was fair, she complaining only of a little debility and anorexia. These symptoms could, it seemed to me, be as much attributed to her long confinement in a hospital ward as to the throat condition itself. The latter caused very little irritation and no cough. Examination showed a typical picture with enlargement of the tonsils, but no acute inflammatory condition. The diagnosis was confirmed by the use of the iodine solution and microscope, as previously described. The leptothrix threads, the amyloid bodies, and refractive granules were all present in considerable numbers.

The treatment consisted in the application of the cautery as recommended. Immediate improvement followed, though she was obliged to leave town before the cure was complete. In this case both tonsils were affected, but no other area.

AN UNDESCRIBED DISEASE: POSTERIOR RECTOCELE.[1]

By GEORGE E. ABBOTT, M.D.,
NEW YORK.

Mr. President and Fellows of the Alumni Association: In presenting this short paper upon a rectal condition which I cannot find described, or even mentioned, in any of the books I have consulted—among them some of the most recent authorities—I feel sure that any fallacy of observation will be skilfully criticised, and any false claim of originality will be leniently dealt with, by my associates of this Alumni.

I therefore present to you the following remarks upon that condition which I believe to be fairly styled, Posterior Rectocele.

Before beginning to explore a new field, let me for a moment carry you over the old, familiar ground of vaginal, or anterior, rectocele.

Let Fig. 1 represent a large, thin-walled, rubber tube

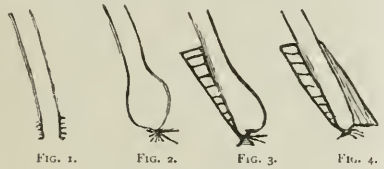

Fig. 1. Fig. 2. Fig. 3. Fig. 4.

in upright position, with a current of water running through it. Now, with no obstruction at its end, we have no pressure upon its walls, and no bulging of its circumference. For the sake of future argument this shall represent the condition of the bowels with diarrhœa, and a paralysis of the sphincter. In Fig. 2 we have tied the end of the tube with a broad tape, or sphincter, or rubber band, and having thus, as it were, restored the contractile tone of the sphincter ani, we get above the tape, the pear-shaped bulging.

Fig. 5

In Fig. 3 we have cemented to its posterior wall a wedge-shaped splint, base upward. This prevents the bulging upon the wedged side of the tube, but the bulging still protrudes anteriorly.

Let me, in Fig. 4, cement another wedge, anteriorly, base downward, and with a few adhesive straps of facia, we shall prevent all bulging of the rubber tube.

Now allow me to turn this vertical Fig. 4 into a horizontal position, and in Fig. 5 we shall find that our rubber tube will quite well represent the rectum, with the first wedge as the sacrum and coccyx, while the second wedge will represent the perineum.

Let us now lacerate our perineal wedge, with its accompanying retractions and atrophies, and we again have Fig. 6, our old friend, vaginal or anterior rectocele.

But suppose the anterior wedge remains intact, as is the case in the normal female, and almost without exception in the male, and also conceive that the posterior wedge be lacerated, or that which is a mechanical equivalent, that it be carried upward, away from the constrictive sphincteric band, so that a space be left unsupported; then it must be evident to all, that a bulging posteriorly, or a *posterior rectocele*, must take place to a greater or less degree, as in Fig. 7.

All of you must have observed how much the presentation of the vulva and anus differs in different patients, even in a good Sims position. In some patients the vulva is right before one, easy of access—and then again it is far forward between the thighs, difficult of access, even though the knees be carried well upward against the chest.

Now, in the measurements I have taken I find that the

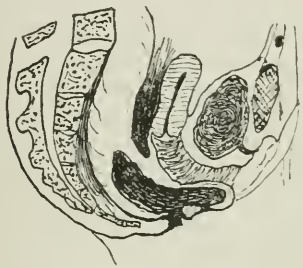

Fig. 6.

distance from the coccyx to the anus varies very much; from less than two to over three inches, making quite a deviation in length of the posterior rectal support from its buttress, the sacrum and coccyx, to its outlet the anus.

Yet this is not the chief element in this disease. The principal factor seems to be the quality of the tone and

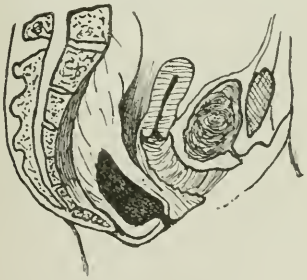

Fig. 7.

strength of the conjoined tendon and fascia attached to the coccyx. In some this is thick and stout, irrespective of length, while in others it is thin, yielding, relaxed, and undertoned.

In those patients who have this latter condition, especially if combined with a well-buttressed anterior wall, and an overtoned, unyielding sphincter ani, we have gradually forming a posterior rectocele caused primarily by the firm, unyielding sphincter, and secondarily by the well-supported anterior wall, and especially by the unsupported, or but slightly supported, posterior wall, which yields before the expansion of the accumulated fæces, and is fatigued, and prostrated, and relaxed by its own efforts in the unequal conflict of expelling the constipated contents of the rectum; the recto-coccygeus muscle also, being overstrained in its efforts to draw the pouch of the rectum upward over the fecal mass, has a semi-paresis set in.

Of course, one would not expect to find that marked

[1] Read before the Alumni Association of the Woman's Hospital of the State of New York, 1891.

pouching which often exists in the more relaxed and pliable anterior or vaginal rectocele; yet it is, at times, well marked both in male and female patients, and I am sure I have in past years seen this condition without really recognizing it.

Now, the unfortunate possessor of such a posterior rectocele will, of course, at first complain of constipation—later of the necessity of severe straining; then cathartics and injections play their part, when hæmorrhoids, fissures, slight bloody stools, and soon the patients tell you that they have had to assist themselves with their own hands, by pressing upon the posterior rectal wall just below the coccyx, in precisely the same manner that a patient with a cystocele places her fingers within the vagina and lifts the base of the bladder in order to empty it; and finally confesses to having to cover the finger with the toilet paper and introduce it into the rectum and so unload the bowels, the moisture having all been reabsorbed from the long-retained fæces.

I am not sure but that when the rectum is empty this bagging of the posterior rectal wall *in the male, may give rise to an internal cystocele, as it were, and allow of a partial retention of urine, causing an ammoniacal cystitis, and by a partial prolapse of the prostate gland cause a poor circulation and passive engorgement of that organ.*

The treatment I believe to be simple, but it must be first thorough and then faithfully carried out.

First, I would thoroughly overcome the obstructing sphincter to obtain the condition of Fig. 1. This, by one or more stretchings, must be carried to that degree which shall be even subnormal as to resistance, so that the contents of the bowels may easily pass its portal with as little as possible of the forcible pressure of the abdominal recti, which causes such a strain upon the posterior rectal wall.

Secondly, the bowels must for weeks be regularly moved, and be of at least a semi-solid consistence. If the rectum can be kept empty by a movement night and morning, so much the better.

Thirdly, the faradic current below the coccyx, and up and down the spine, will restore the normal tone of the parts. I like the action of the Brush electrode; also an intra-rectal electrode. *I believe the longitudinal scoring of the rectum, either with the hot iron or acids, would be bad practice until the tone of the coccygeo-anal wall had been restored. This should first be done, and then the relaxed rectal pouch, being again supported by its natural buttress, may be operated upon as seems necessary.*

I have now touched upon the main points of a condition which, so far as I know, has not before been described, and which I believe may be fairly denominated Posterior Rectocele.

It has been suggested that posterior rectal hernia would be a more appropriate term. But as there is no possibility of its becoming strangulated, and as we so often speak of the vaginal or Anterior Rectocele, I have retained the term Posterior Rectocele.

19 East Sixty-first Street.

The Laughing Plant is the name of a plant growing in Arabia, and is so called by reason of the effect produced upon those who eat its seeds. The plant is of moderate size, with bright yellow flowers, and soft, velvety seed-pods, each of which contains two or three seeds resembling black beans. The natives of the district where the plant grows, dry these seeds and reduce them to powder. A dose of this powder has similar effects to those arising from the inhalation of laughing-gas. It causes the most sober person to dance, shout, and laugh with the boisterous excitement of a madman, and to rush about cutting the most ridiculous capers for about an hour. At the expiration of this time exhaustion sets in, and the excited person falls asleep, to awake after several hours with no recollection of his antics.—*Medical Times.*

OXYGEN AS A DISTINCT REMEDY FOR DISEASE, AND A LIFE-SAVING AGENT IN EXTREME CASES.

By A. W. CATLIN, A.M., M.D.,

Attending Physician, St. John's Hospital, Brooklyn, N. Y.

Oxygen, although known to the profession for many years, as a remedial agent, has not, until the last decade, received in any sense its true recognition. Like many other agents, it has had its history of tentative experience, only to be relegated to the list of such remedies as are either too expensive, too cumbersome, or too uncertain in their effect, to retain their hold in the mind and heart of the earnest practitioner.

This also means that, in common with other agents having similar experience, it has been left in the hands of a quasi-professional class—non-scientific—whose use of it resulted in no practical good. If, in this article, proof can be adduced to show that this agent is not only a potent remedy, but has a far wider field than is commonly supposed, the object of the writer will be attained.

Primarily, and for a long time exclusively, this agent has been recommended in lung difficulties—more especially to relieve the dyspnœa and cyanotic conditions following in the train of a pneumonia, where a large amount of lung-structure is involved. Another way of stating the fact that its use was deferred until the disease was far advanced, the strength exhausted, and the recuperative powers in abeyance; in other words, a *dernier ressort*, as a palliative and not as a curative.

Fortunately, however, for our patients, another view is now taken of this life-giving agent, and to-day we recognize the fact that if we can, with a limited lung-capacity (such acute but self-limiting disease being present), pass more or less continuously the same quantum of oxygen into the blood as is normally required, when no disease is present, we practically lift our patient to the plane of health so far as functional activity is concerned and give him a hundred-fold more strength to battle with than before. We emphasize this question of functional activity. Disease means limitation and ultimately, if not checked by natural or other means, suspension of such activity. Where, therefore, the natural forces, if sustained, are the curative agents, it is eminently proper to secure by every means in our power a continuance of this activity throughout the whole system until the disease has run its course, and thus conserve the reparative powers so necessary in convalescence.

How often we hear the sad expression, "The disease was virtually conquered, but our patient succumbed because the vital forces were too much exhausted to go on with the recuperative effort;" a statement which we believe is destined to become less and less frequent as the profession realizes the part that this potent factor is to play in the future of medicine. It is our desire to show: 1. That oxygen is the most sure and satisfactory stimulant we have. 2. That by being exhibited through the lungs, and not by the stomach, its entrance into the circulation is much more certain and immediate. 3. That its effect, felt primarily upon the heart, is almost as quickly seen at the nerve-centres and in the digestive organs. 4. That it is pre-eminently the remedy for profound shock, either from hemorrhage or nervous drain, where vitality is at too low an ebb to take up the intricate history of assimilation and repair.

Case I.—Mrs. G——, six months pregnant, after being subjected to a protracted and severe strain by the constant care of a child critically ill with diphtheria, was suddenly taken with a flooding. The hemorrhage was so great and the shock so profound by the time medical aid reached her, it was impossible to move her from the lounge to the bed. A tampon was applied and hypodermics of brandy and strychnia resorted to. All attempts to nourish her by mouth failed. Stomach would not tolerate even water. Pulse scarcely perceptible at wrist. Respiration shallow, eyesight dim, voice but a whisper.

Tampon controlled the hemorrhage, brought on some uterine contraction, and the hypodermics, which were continued, produced some reaction.

In the course of a few hours counsel was sought, to determine the best course to pursue to relieve the uterus of its contents. It was advised to remove tampon and put on forceps if dilatation would admit of it, but the better course was finally adopted of applying the faradic current to the fundus as the last part of the tampon was removed, which caused the uterine wall to contract firmly upon its contents, brought the head promptly down, and quickly completed the birth of child and placenta without any loss of blood, a vital consideration in view of the well-nigh moribund condition of the patient—a result which certainly could not have been obtained if the old method of entering the cavity of the uterus with the forceps had been resorted to, and would certainly have put the life of the prostrated mother in imminent peril. Continuance of the current held the womb tightly contracted, and to use the patient's own words subsequently, gave her power and conscious strength here which she was unable to supply herself. Prostration, however, continued absolute; the stomach still refused nourishment or liquid in any amount, and the character of the pulse indicated a cardiac failure which made the condition very alarming. A fresh cylinder of oxygen was then sent for and its administration watched with the deepest interest. Continuous inhalations were given, and almost immediately a restful, calm expression came into the face. The pulse steadied at the wrist, and soon little naps of refreshing sleep announced that our king of stimulants was doing its work at the nerve-centres. In an hour a teaspoonful of milk and lime-water was taken and retained, and very soon another, till complete tolerance was established; and this in turn was followed by a demand for food, showing that our life-giving agent had reached this vital centre and that powers of assimilation were eager to do their work. The inhalations were continued with longer and longer intervals as the strength returned, convalescence being established and recovery assured in much less time than the gravity of the case gave us reason to expect.

Case II.—Seen in consultation. Mr. H——, a gentleman thirty-eight years of age, of good average health, taken during the grippe period with the prevailing influenza—exasperating bronchial cough and neuralgia; attack resisted treatment and patient gradually weakened, till a passive pneumonia announced itself and grave doubts were entertained of his recovery. At this point oxygen was advised, and almost immediately the patient announced himself as feeling better. The agent was continued and recovery followed in the line of restored functional activity. He breathed better, had refreshing sleep, began to demand and assimilate nourishment, and threw off the passive congestion because of renewed strength.

Case III.—Miss S——, twelve years of age, a scholar at one of our large institutions, naturally of a very nervous temperament, had the duty of speaking in public before the school required of her—a task which so disturbed and excited her, that after the effort was over she was obliged to return home and go to her bed; extreme nausea was present and absolute nervous prostration. Respiration irregular and sighing, pulse feeble and intermitting; patient tossed restlessly from side to side, and stomach refused all food. All other means failing and the patient becoming more and more exhausted, oxygen was exhibited, with immediate benefit, a calm quiet sleep coming—first in brief naps, then more continuously—while the heart steadied and the sighing breathing gradually ceased.

After the sleep of restoration the digestive centres balanced and food was given in small quantities. The gas was continued for a few days, with small but repeated doses of nux vomica, and a rapid recovery made

Case IV.—Seen in consultation, and best told in the words of the attending physician, Dr. Alexander Hutchins. Mrs. W——, anticipating her confinement, December 20th, was attacked with double pneumonia, November 16th. She had endured great discomfort from uterine tumor, the breathing in the recumbent position being much impeded, and the dyspnœa from the pneumonia, added to the restraint by pressure on the diaphragm from below, enforced an erect sitting posture to breathe at all. Her condition was held to be very grave and the prospect of a premature delivery imminent. Labor came on suddenly on the 24th, eight days after the pneumonic seizure, and though the labor was rapid and energetic, the patient was almost moribund immediately after the expulsion of the child. Prompt obedience to the peremptory command of her physician in taking forcible inspirations, restored her breathing. The loss from hemorrhage, the heart strain, the dyspnœa from the pneumonia, all contributed to a profound shock and depression which the various forms of stimulants failed to overcome. Inhalations of oxygen were resorted to, with manifest immediate relief, about thirty hours after the completion of her labor. The inhalation was continued during sleep and while awake, with very rare intermissions, for forty-eight hours, and was kept up less continuously for ten days. It was a substitute for all other medication. The recovery was complete.

It can hardly be questioned that the oxygen saved her life. The insufficient aëration and the weakened circulation would have made absorption from the stomach impossible, stimulants alcoholic or diffusible would have been of no avail, no food could have been digested or assimilated. The ease of the administration of the oxygen was no unimportant matter in this case. It required no effort whatever on the patient's part. The persistance with which it was continued was in part due to the appreciation by the patient that the intermittent use of the inhalation diminished her comfort. The case was asthenic from profound shock. The inhalations of course were never deep. As the lung cleared the inspirations were deeper and the need of the oxygen became less imperative and less frequent. The support of the patient was maintained with uniformity by reason of the steadiness of the oxygen stimulation. The neatness and repose of the treatment are not trivial matters. The stimulation through the lungs, and not by the stomach, is in the course of natural action, and not indirect action.

Case V.—Miss B——, aged nine years, shortly after her return to the city, in September, 1889, was taken with headache, chilliness, and general malaise, gradual rise of temperature, and an increasing prostration that compelled her to take to her bed. The case was diagnosed as one of mild typhoid, but soon developed, at the end of two weeks, so much cardiac weakness as to make prognosis grave. Patient naturally frail and anæmic, complained of sense of oppression and cold extremities. Lips and nails were blue, and at times a dusky hue could be seen over the whole countenance—prostration increasing with growing inability to nourish. The unfailing friend—oxygen gas—was promptly secured, and continuous inhalations given. Heart responded at once—cyanotic condition cleared up, and a gradual but steady improvement ensued. Fever ran its course, but with the oxygen, which was continued two weeks, there was a conscious strength to battle with the disease, which meant victory in the end.

In the above cases, selected from a large number, the principal points claimed for this agent are exemplified, but we desire to emphasize this fact—for it is a fact—that while oxygen is undoubtedly a great burden lifter from the heart in cases of dyspnœa and unsufficient aëration, it is something far more to the nervous system if given with a free hand, as we have indicated. Nature's sweet restorer never has been so successfully wooed as by this suitor, and when the ravelled sleeve of disease has been gathered up by this most potent remedy we see following immediately in its train all the natural processes of repair, wherever such is possible. This then is the point we

desire to lay stress upon: Oxygen is something far more than a mere palliative—a reliever of symptoms, or an urgency-resort to keep the heart going a little longer. It is a distinct remedial agent, and will save life over and over again in such cases where the natural forces only ask for time and functional liberty to do the work.

It is hard to understand the prejudice that has existed so long in the minds of the profession in regard to this agent, and even to-day has to be combated with not a few. Slowly but surely, however, it is being recognized in its mission of helpfulness, and we believe the day is not far off when it will take rank with electricity as one of the two great life-saving agents of our day and generation. Among the cases narrated it was manifestly shown in one, that life was saved first by the localized power of electricity controlling hemorrhage, and later on by the diffused and true stimulants of oxygen, whereby functional activity was continued.

It only remains to add the results of experience as to the best method of exhibiting the agent.

If you would get your best results, you must administer the gas at first freely and continuously, especially in those cases of profound shock where the depleted centres of life must have this true stimulation offered unremittingly, if they are to be encouraged to take up their duty again. Theoretically, only a certain quantum of gas can be absorbed—but facts are stubborn things, and the fact here is, that far more oxygen is absorbed by the blood than has been supposed possible. The only indications for a suspension of its use is a condition at once recognized by the patient, viz., super-exhilaration and dizziness—and this limitation is rarely reached in these extreme cases where the inhalations are not as deep or prolonged as they are when the strength returns and the demand for the stimulant naturally begins to limit itself. In other words, the patient once instructed in its use and conscious of its helpfulness, is the best guide in its administration and can be safely allowed to breathe it ad libitum. The fear is, they will not get enough, not that they will get too much. This, of course, implies that the pure gas mixed with nitrogen, two parts of the former to one of the latter, is being used.

In cases of extreme debility it has been found expedient to draw the gas through the wash-bottle into a small black rubber bag, holding say about five gallons, and then, affixing a large mouth-piece and short tube to this, place it on the pillow by the side of the patient. This saves much strength in the effort of inspiration, and is the easiest way to present it where every particle of the patient's capital must be preserved. Be sure to use fresh gas. Cylinders that have been kept charged over two months show, by the flat taste and odor, that prolonged compression changes the character of the gas and probably, to a degree at least, devitalizes it. Its power as an antiseptic and disenfectant we are all aware of, and is markedly seen in diphtheria where the breath is so foul, and it has been decidedly helpful in the severe types of this disease as a coadjutant to corrosive sublimate. If, after prolonged surgical operation where the patient has been thoroughly saturated with the anæsthetic and, as a consequence, convalescence is tardy and unsatisfactory, oxygen were to be promptly administered, we would find the reparative action wonderfully enhanced and local results far more gratifying.

The objection so often raised to it as a cumbersome remedy, not easily obtained at short notice, no longer holds, for depots are established all over our large cities.

There are many other conditions under which oxygen can be exhibited, always with relief, even if the nature of the case is necessarily fatal; and at the end of a hopeless struggle, when the grim visitor is at hand to claim his own—the poor weary body—it is no small thing to say, that it relieves needless suffering, smoothes the dying pillow, and gently invites into that dreamless sleep, that knows no waking here."

Clinical Department.

LOSS OF AN EYE FROM PURULENT IRIDO-CYCLITIS SET UP BY A BIRD-SHOT.

Enucleation for the Prevention of Sympathetic Ophthalmia; two Eyelashes Found Attached to the Shot.

By DAVID WEBSTER, M.D.,

Professor of Ophthalmology in the New York Polyclinic and in Dartmouth Medical College; Surgeon to the Manhattan Eye and Ear Hospital, New York, etc.

Mr. J. D. C——, aged fifteen, was brought to my office by his family physician on account of an injury of his eyes on September 4, 1890. In my absence, my associate, Dr. S. M. Payne, saw the patient and elicited the following history: Two days previously, Mr. C——, while out shooting birds, fell against a rock with his loaded gun in his hand. The gun went off as it struck the rock and while his face was within a foot or two of its muzzle. The charge struck the rock and rebounded with great velocity, several of the shots embedding themselves in the skin of his face and forehead. His brother picked out several from beneath the lids of his left eye. One had produced a central abrasion of his left cornea, and one had penetrated his right eyeball, destroying the sight immediately. His physician had been sent for upon his return to his home and had removed such shots as he could find, and had applied atropine and iced cloths locally with the view of preventing or allaying inflammation until the patient had sufficiently recovered from the shock to be brought to the city, a distance of some fifty miles.

Dr. Payne noted the following conditions when he first saw him: "R. V. = sees fingers at three inches above the horizontal meridian. L. V. = $\frac{20}{20}$.

"The right eye has been painful and sensitive to light ever since the injury. There is a perforated wound of the cornea near its temporal border and a corresponding opening in the iris. The lens is cataractous, and with the ophthalmoscope no reflex from the fundus can be obtained. There is irido-cyclitis as shown by chemosis and by pain on pressure upon the ciliary region above. The tension is increased (+ 1.) and there are the remains of a mostly absorbed hemorrhage into the anterior chamber. The ophthalmoscope shows that the lens and fundus of the left eye are normal; but there is a central abrasion of the cornea, and several ecchymotic spots are seen on the conjunctures."

Dr. Payne, appreciating the gravity of the case, expressed the opinion that the eye would have to be enucleated; but thought it wise to fortify himself with a consultation. He therefore sent the patient to Dr. Noyes, who kindly examined him and sent him back with the following written opinion: "There can be no doubt about the shot being in Mr. C.'s eye, but I would treat the case expectantly, using atropine and cold water. The question of enucleation can be decided later. I am not in favor of its immediate performance. Increase of tension does not call for any special interference. If reaction should become considerable, leeches can be used, and the pain can be controlled by phenacetine."

I first saw the patient on the evening of the 6th, four days after the accident. The conditions were the same as described above, except that the vision of the right eye was reduced to perception of light. The iced cloths and atropine were continued; the patient was leeched; and phenacetine was given for the relief of the pain.

On the 8th, or six days after the injury, as the eye was in every way worse, the iris having a purulent look, the chemosis being greater, and the ciliary tenderness and tension of the eyeball were still more increased, I advised enucleation. Dr. Thomas R. Pooley was called in and, after careful examination, unhesitatingly advised the same. On the afternoon of the same day, aided by Dr.

Thomas R. Pooley, Dr. S. M. Payne, and Dr. E. A. Kirkpatrick, I enucleated the eyeball, the patient being under ether.

The recovery was normal, and in due time the patient was furnished with an artificial eye.

On September 16th, the vision of the left eye was $\frac{20}{20}+$. The enucleated eyeball was put in Müller's Fluid and given to Dr. Bennet S. Beach for microscopic examination. The following is his report:

"Cornea shows track of wound near sclero-corneal junction, filled with fibrinous material and pus-cells. Iris inflamed. Layer of pus-cells over anterior surface. Anterior synechia at point of injury to cornea. Some of pigment-cells of iris carried forward into wound. Iris shows perforation at this point. Lens surrounded by layer of pus-cells. Portion adjacent to track of wound degenerated. Ciliary bodies infiltrated with pus cells. Large amount of plastic exudation posterior to lens which has been pushed forward obliterating anterior chamber. In the centre of the exudation was a small piece of lead. This was surrounded by a thick layer of pus-cells. Attached to the lead were two eyelashes. Retina, totally detached."

The case as reported above tells its own story, and scarcely needs any comments. It was certainly a remarkable and surprising thing that the shot should have carried two of the eyelashes into the vitreous humor along with it. I suppose that the chances were nearly all that sympathetic inflammation of the fellow-eye would have been caused if the inflamed and sightless eye containing the foreign bodies had not been enucleated.

BILOBED UMBILICAL HERNIA—OPERATION —RECOVERY.

By J. M. SLIGH, M.D.,

GRANITE, MON.

I REPORT the following case, not because successful operation for umbilical hernia is rare, but for the reason that this case presents some features of rare occurrence in an anatomical point of view.

May 5, 1891, Mrs. M. J. McD , widow, aged thirty-eight, about two hundred pounds in weight, sent for me, and upon arrival I found her suffering from intense colicky pains, localized in the region of the umbilicus, and attended with nausea, and an expression of anxiety or apprehension. Examination revealed a temperature of 99¼° F., pulse 108, and a tumor about the size of an ordinary orange involving the umbilicus. She informed me that the tumor had existed about six years, sometimes being larger than at other times, occasionally giving rise to pains of short duration, and that when the tumor was larger than usual, upon lying upon her back it would decrease in size, this decrease being accompanied by a dragging sensation and a gurgling sound. This time the pain had lasted for two days, there had been no movement of bowels during that time, and the patient had vomited twice. The tumor was flat on percussion over its entire surface, and of a semi hard, doughy feel. Ordinary efforts at reduction failing, and believing the contents of the tumor to be mainly omentum, I ordered an anodyne, rest on the back, and hot, moist applications continuously until I should see her again. On the morning of May 6th her condition was unchanged, and I recommended an operation to which the patient readily assented. At 5 P.M. May 6th, assisted by Drs. W. I. Power and W. H. Allen, I performed herniotomy by a longitudinal incision over the tumor in the median line. Upon cutting through the skin about three drachms of clear, watery fluid escaped, and the cellular tissue was exposed, intimately adherent to which, by organized bands, was a mass of omentum, a part of which, about the size of an English walnut, was nearly black and apparently as hard as a stone, the cicatrix of some previous inflammatory action. The adhesions were broken by my fingers and the handle of the scalpel, and the constricting point searched for. The umbilical opening was large, circular in form, and did not appear to constrict the tumor in the least, notwithstanding which I was unable to reduce any part of the protruding omentum. The cause was found to be a longitudinal band, fibrous in character, to the sides of which, and above it, the omentum was adherent, rendering the hernia bilobed. Dividing the omentum in the median line, and separating it from the constricting band, I ligated the whole protruding mass, in two portions, cut it off, returned the stumps with the ligatures to the abdominal cavity, cut out the constricting band, scraped the edges of the umbilical opening, and drew the sides in opposition by two strong sutures, tied and cut short.

The outer wound was closed by seven deep sutures, and the usual dressings were applied. All sutures and ligatures were of silk, soaked in carbolized water, and the operation was made under aseptic conditions rather than antiseptic.

Twenty-four hours after the operation the patient's temperature was 102½° F., and pulse 120, both of which became normal within the following twenty-four hours, after bowels had been freely moved by three or four doses of salts (Magnesii Sulphate). Six days after the operation the dressings were removed, the sutures taken out, and the wound found to be healed by first intention, excepting a very small opening at the lower extremity, through which some suppuration subsequently occurred.

Ten days after the operation the patient was out of bed, and three weeks after the operation she resumed her household duties.

The points of special interest in this case appear to be the entire absence of a peritoneal covering, and the presence of a constricting septum or band, forming a bilobed hernia, together, probably, with absence of unfavorable symptoms arising from buried sutures and ligatures of silk.

Progress of Medical Science.

Subcutaneous Injection of Arsenic.—It is again asserted that the subcutaneous injection of arsenic is less poisonous than its administration by the mouth. Arsenic locates itself in the stomach, the liver, and the upper intestines. Introduced into the skin, arsenic enters the general circulation without being arrested at the liver, which is undoubtedly the elected spot of mineral salts. It is observable that Fowler's solution is unsuitable for subcutaneous injection; it produces an irritation of the connective tissue by the presence of free arsenious acid. A solution of arseniate of soda, which is stable, provokes no more irritation than pure water.

Anatomy of Tubal Pregnancy.—Two cases are recorded occurring in the practice of Dr. Landau. In the first case the patient died in a few minutes after the arrival of the physician. In the second the patient's condition was so poor that no operation could be attempted. But in spite of rupture the patient rallied and made an excellent recovery. In Case I. the autopsy revealed a rupture of the right tube. The decidua was removed from the uterus. In Case II. pieces of decidua came away. Careful microscopic examinations were made of the specimens, and from these the following are formulated: In tubal pregnancies occurring in the fourth and fifth week we find—1. That the endometrium is about to become changed into a decidua. The compact layer, the so-called layer of Friedländer, is not fully formed. 2. The superficial epithelium of the decidua uterina is intact as late as the middle of the second month, although its form is materially changed. 3. The vessels which are found in the superficial layers of the decidua uterina are in all probability arteries and veins. 4. The ovary and tube on the unimpregnated side remain unchanged. The ovary containing the gravid corpus luteum is enlarged

5. The cause of tubal pregnancy may be assumed to be due to a diverticulum in the walls of the tube or a marked tortuosity of the same. 6. That portion of the tube not included in the impregnated sac usually remains unaltered. 7. A decidua tubaria vera is formed upon the mucous membrane of the tube, having its greatest amount of development at the poles of the ovum. The superficial epithelium of the decidua serotina disappears, and is replaced by the endothelium of the freely communicating capillary vessels. 8. In the majority of the cases no decidua tubaria reflexa is formed. If one is formed it differs entirely from the uterine reflexa, owing to its small number of vessels. 9. The attachment of the chorionic villi to the decidua tubaria is extremely loose in the beginning of the pregnancy, but in some situations a complete union between the two is found. 10. The epithelium of the chorionic villi is of the three varieties. The maternal capillary endothelium lies external to a double layer of fœtal epithelium. 11. The intervillous spaces are composed of dilated maternal capillaries, whose walls are not penetrated by the chorionic villi.—*Medical and Surgical Reporter.*

Nephrorrhaphy and Its After Effects.—This operation has been performed fourteen times by Dr. Tuffier for movable kidney. There are three orders of symptoms produced by this disease: 1, Pain; 2, gastric disturbances; 3, neurasthenia. There are, therefore, three clinical types of movable kidney. The painful form, with or without hydronephrosis, is the most frequent and is the most favorable for treatment, since in ten cases pain disappeared entirely after the operation and in three other cases pain was much relieved. The dyspeptic form is less common (two cases) and is accompanied by enteroptosis or hepatic lesions. The neurasthenic form is also rare; it includes the entire gamut of nervous symptoms, as well as hysteria. There are two absolutely distinct etiological varieties from a therapeutic point of view: the simple movable kidney or traumatic displacement, which is a true dislocation; a forcible hernia, the rest of the abdominal belt being unaffected. Operation in such cases is the triumph of nephrorrhaphy. The movable kidney with complications is a slow and progressive displacement, preceded, accompanied, or followed by Glenard's enteroptosis. In such cases the nephroptosis is only incidental, there is a weakening of the abdominal walls, which should be supported by a belt and invigorated by massage. Out of ten patients operated on, after an interval of more than four months, one only was attacked by congestive outbreaks. The nine others, all recently examined, have firm cicatrices without any tendency to hernia; the kidney is fixed and forms part of the abdominal wall, but may be readily distinguished over the greater part of its extent. Pain has been relieved in every case with one exception, and in that case there is enteroptosis. Such results are encouraging. M. Tuffier believes that nephrorraphy should maintain its position as a legitimate operation in renal surgery. It is a mild operation, as in 149 cases the mortality is only 3.4 per cent. It is efficacious, since out of seventy-three typical operations in eight per cent. the patients were either cured or much relieved. The success would be yet greater if a careful selection of cases were to be made.—*L'Union Médicale.*

Resection of the Lung.—Dr. Tuffier presented at a recent meeting of the Société de Chirurgie, a patient on whom he practised in March last excision of the summit of the right lung for localized tuberculosis, and gave the details of the operation. Before attempting the extirpation of the parenchyma of the lung, Dr. Tuffier made several experiments in the amphitheatre on ligature of that part of the organ. Through a small intercostal incision he tried to separate the pleural covering from the lung and get a ligature around it, but although he found it easy enough to detach the pleura above, in front, and behind, it was not so on the inside, and as the thoracic canal and the phrenic nerve are intimately attached at that point to the pleural layer he was afraid of including them in the ligature, and consequently abandoned all attempt in this direction, and decided on performing resection of the diseased parts. And this decision gave rise to a series of questions to which he could not find a satisfactory answer at the moment. How would the lung-tissue bear a ligature? What are the mode and rapidity of reparation of the loss of substance? What should be feared from the innumerable vessels of the organ? How would the void left in the thoracic cavity be filled? In order to fix himself on these important points he resected the summits of the lungs of several dogs, and the result of his experiments was that the wound rapidly healed and that the void was quickly filled by expansion of the parenchyma, provided the part resected was not too considerable. His first patient was a man on whom in November last he performed the radical cure for hernia of spontaneous origin. The tumor occupied the sacral intercostal space. When he had made the incision he detached the pleura with his finger, and pushed it up to the summit, and explored the region, as the man's appearance was such that tuberculosis was suspected. The lung felt velvety to the touch, and if any induration had been present it would have been easily detected. The wound was then closed, and in a week the patient was cured of his hernia, and experienced no inconvenience from the exploration. In a second patient resection was really practised. The man, aged twenty-five, was of stout build, and enjoyed perfect health until two months ago, when he was attacked with cough, night-sweats, and tuberculous laryngitis, and for which he entered the hospital. Auscultation revealed the following symptoms: At the top of the right lung submatité, respiration rude and jerky, expiration prolonged, and dry crepitation in coughing; the left lung was perfectly healthy, and the patient, being made aware of his condition, accepted the risks and perils of operative interference, especially as medical treatment but little changed his condition. The *modus operandi* was as follows: A cushion being placed under the back so as to efface as much as possible the subclavicular fossa, an incision was made through the second intercostal space to within half an inch of the sternum; the great pectoral and the intercostal muscles were similarly incised, and the pleura brought to view, which being cut in turn, the tissue of the lung appeared. The operator then passed in his finger and detached the serous membrane above and without with comparative ease, but when he reached the inside the membrane yielded, and immediately a hissing sound occurred, indicating an escape of air or the formation of a pneumothorax. The finger was applied to the spot, and subsequently a plug or iodoform gauze. Continuing the operation, M. Tuffier passed his finger behind the summit of the lung, and seizing the tissue with a special flat forceps drew it forward, threw a ligature around it and fixed the pedicle to the periosteum on the internal side of the second rib. The muscles were then sutured and the wound dressed with iodoform. The piece resected was examined, and in its centre was discovered an induration of about the size of a small walnut, and surrounded with tubercles in which bacilli existed. The man made a rapid recovery, and a minute auscultation of the lung showed that the respiratory murmur, although a little weakened, was present throughout the whole organ without revealing the slightest sign of a pleural effusion.—*Medical Press.*

Sounding the Depths of Medical Practice.—The medical adviser of a friendly society in Bath advertises that he will undertake the medical treatment of all and sundry at the economic rate of "one penny weekly for adults, and one halfpenny for children." We ought, we suppose, to be gratified that medical fees have not yet come down to decimals of the humble penny.—*Medical Press.*

New York, August 29, 1891.

FUNCTIONAL ALBUMINURIA.

THE subject of functional or intermittent albuminuria is one that continues to hold the interest of physicians, despite the frequent contributions to it. This is natural, because the matter is one which is not yet satisfactorily settled, and because upon it depend the future of many individuals as well as the business interests of many large corporations. In a recent article entitled "The Varying Significance of Intermittent Albuminuria," by Dr. John Winters Brannan (*New York Medical Journal*, July 4, 1891), the subject is presented in a comprehensive and systematic manner, while in an earlier article on "Albuminuria in Persons Apparently Healthy," by Dr. William B. Davis (MEDICAL RECORD, June 13, 1891), many facts of practical importance are collected.

It is conceded on all sides that there is a functional albuminuria which is usually intermittent in character, and which does not necessarily indicate structural disease of the kidneys. The questions to be solved are the pathology of this condition, the methods of recognizing and treating it, and of deciding as to the prognosis. With regard to the pathology, an immense number of observations and studies have been made. These all go to show that functional albuminuria may have widely different causes. Although in a single case several factors may be at work, they can be broadly differentiated, according to Dr. Brannan, into three classes: 1, the dyscrasic, 2, the mechanical, and 3, the neurotic.

The various subdivisions are shown in the following scheme:

Class I. Dyscrasic.	Hetero-albuminæmia. Digestive. Oxaluric. Hepatic. Gouty.
Class II. Mechanical.	Cyclical. Albuminuria of adolescents.
Class III. Neurotic.	Mental anxiety. Intellectual effort. Excessive physical fatigue.

Under the dyscrasic class come those forms due to the presence of dialysable albumins in the blood, which in turn are due to deficient activity of the skin, excess of albumin in the blood from various causes, deficient action of the liver, digestive disturbances, etc. The albuminuria of persons with a gouty tendency, or oxaluria, comes under this head.

Under the head of mechanical types of albuminuria come the cyclical albuminuria of Pavy, which is found in persons of weak circulation and low vaso-motor tone. The albuminuria is thought to be due to a venous stasis. Such patients have albuminuria a few hours after rising, owing to the fact that an increased weight of blood is thrown on the renal veins.

Neurotic albuminuria occurs in persons who suffer from severe worry and mental strain. It is thought to be due also to a weakened state of the renal vaso-motor centres causing venous stasis, so that there is here an underlying mechanical element, as there is also in the albuminuria following physical exercise.

As to the frequency of functional albuminuria, Dr. Lambert, quoted by Dr. Davis, says that among apparently healthy persons applying for life insurance the percentage of cases of albuminuria is two per cent., rising to five per cent. in very cold or very hot weather. Dr. Brannan says: "In the course of the last seven years I have examined 365 persons, mostly males, for life insurance. Of this number, 54, or 14.8 per cent., had more or less albumin in their urine. This is probably a much larger percentage than would be found in the general population. The same fact has been noted in England, and Dr. Rabagliati explains it by saying that the well-to-do who apply for life insurance suffer more from urinary diseases than the ordinary population, mainly because well-to-do people eat and drink too much. For the purposes of comparison, I examined, a few years ago, the urine of 100 consecutive male patients at the Roosevelt Hospital Out-door Department. In not more than five per cent. did I find albumin without other symptoms of Bright's disease."

Thus it may be assumed that in adults the percentage of cases of functional albuminuria ranges from two to five.

With regard to the prognosis of such cases, opinions have to be formed for each individual case. On the whole, it may be said to be favorable, yet the condition is always pathological, and not free from dangers.

General rules for dealing with such cases cannot be better formulated than is done by Dr. Davis in the article referred to.

HOW TO PREPARE ARTICLES FOR THE MEDICAL RECORD.

WE have taken the opportunity at various times to make certain suggestions to our correspondents as regards the method of preparing their manuscripts. A series of golden truths for writers has just been published by Miss Thackeray in *The Epoch*, and the series is so valuable that we beg to call the attention of our contributors to them. The advice applies just as well to medical as to lay writers.

"Let your paper be white," says Miss Thackeray, "of good quality, fit for ink, and let that ink be black. Don't use pencil; the countless hands that finger your manuscript, from the lord high admiral editor down to the printer's devil, will rub and blur it into illegibility.

"Make your writing legible, especially the proper names, even if you have to sacrifice some cherished flourishes and artistic shadings. Eschew shading, a sprawling hand, and a Gillott's pen 404. What is known as the 'literary

hand'—a small compact hand, almost upright—is the best economy of time and space. If you print your proper names with a pen, the editor will be doubly grateful. Use a stub pen if you can, and black ink that will not rub after it is dry. Violet ink, particularly on orange paper, which some authors affect, rubs, fades, and stares the tired editor's eyes out of countenance.

Avoid blots and interlineations as you would the Black Death.

"Six by nine inches is an excellent size of sheet on which to write. Never, never, inflict foolscap upon a long-suffering editor. Foolscap paper is heavy, awkward to handle or put down, occupying too much space, covers the case of the compositor, and jostles and breaks its corners in Uncle Sam's mail-bag. Letter-paper size may be pardoned, especially in a type-written manuscript, but foolscap, especially if it be rolled, is the nightmare of an editor. Several magazines advertise that they will return rolled manuscripts unread; one desperate domestic periodical announces that all such manuscripts will be burned unopened.

"Revision nearly always implies condensation. Strip your manuscript of all unnecessary verbiage, and it will have a much better fighting chance. Carefully count the number of words. I think if I could give the beginner but one bit of advice it would be this: Five hundred words too much will sometimes swamp the ship and sink your craft to the bottom of the editorial waste-basket.

"As to faults of ignorance, it ought to be unnecessary to remind the beginner that no one has a right to inflict a misspelled, poorly-paragraphed, ungrammatical article upon a long-suffering editor. If you can't spell correctly or write grammatically, or punctuate and capitalize with at least ordinary regard for the rules of John Wilson, shut your desk down upon your epic and open your grammar and your rhetoric. You are handicapped in the race."

THE CONQUEROR OF SEPSIS.

Undoubtedly one of the most fruitful and practical fields for bacteriological study at the present time is the search for an agent which will kill infectious organisms in the body, and not cause death to the circulator of these organisms.

Up to the present time, says Dr. Roswell Park, in his Mütter Lectures, "no substance has been discovered whose absolute toxicity is not greater than its relative. In other words, we have not yet discovered that which will not kill in the animal in $\frac{1}{4}$ or $\frac{1}{5}$ of the proportion required to kill bacteria. When we have discovered that one of which this cannot be said, we shall have learned to conquer sepsis. In many respects the serum of certain animals most nearly approaches this desired substance, but this only for certain bacteria. It is, for example, known that anthrax bacillus will not grow upon rat-blood serum, although it will upon serum from other animals. Streptococci will not grow on calves-blood serum—only on rabbit-blood. Within the past few years numerous investigations have been made regarding the antiseptic properties enjoyed by blood-serum, from which it would appear that it affords the greatest protection which our systems enjoy to have circulating in our blood serum of this healthy character.

"Studies like these were begun ten years ago by Koch, who himself carefully tested some two hundred different substances. He then turned over the work to Behring, who has investigated half as many more. Only very recently has any statement emanated from the master or his assistants indicating that any such substance had been discovered. Recent utterances of Koch imply that he thinks he has at last found it, at least so far as animals are concerned."

We can only hope that if Koch has found anything this time, he will not feel compelled to disclose it until the facts are established. A few more disasters like tuberculin would set back scientific medicine fifty years.

OLIVER WENDELL HOLMES, M.D.

Eighty-two years ago to-day that genial writer and kindly poet, and erstwhile physician, Oliver Wendell Holmes, was born in Cambridge, Mass. Although he some years since formally announced his withdrawal from the ranks of the medical profession, and soon after emphasized the fact of his retirement by the gift of his medical books to a public library, yet, as he himself says, in a letter published in another column, he still retains his interest in all matters relating to the profession; and even did he not we should ever claim him as a brother. He may not be a practising physician, but he is still a member of the medical profession; and on this day, when literary societies and friends are pouring in their congratulations, we, as fellow-medical men, claim the privilege of sending him greeting, and of wishing him yet many years of tranquil and peaceful enjoyment of this good world, which he has made both better and happier by the example of his life and by his work.

News of the Week.

A Conference of Hospital Medical Boards.—Dr. Louis A. Rodenstein, of this city, has addressed a circular letter to the medical boards of many of the hospitals in this and neighboring cities, suggesting the formation of an association of hospital physicians and surgeons. During the past few years, he says, such rapid strides have been made in the development of our hospitals, and such important changes made in the management, construction, furnishing, ambulance service, etc., in the different institutions, as increasing experience proved necessary, that, could representatives from the different hospitals be brought together to discuss this subject, much benefit would result to all. If such an association be formed, it is proposed to hold the first meeting in Washington, in September, in conjunction with the Congress of American Physicians and Surgeons. A preliminary meeting to settle the details of organization will be held at the Academy of Medicine, in this city, at an early date.

New York State Society of Railway Surgeons.—The preliminary steps are being taken to organize a society of railway surgeons in New York State. Surgeons throughout the State interested in railway surgery are invited to communicate with Dr. George Chaffee, 201 Forty-seventh Street, Brooklyn.

The Sixty-fourth Annual Meeting of German Naturalists and Physicians will be held in Halle from September 21st to 25th. Among the addresses announced are the following: "The Limits of the Healing Art," by Professor Nothnagel, of Vienna; "The Art of Prolonging Human Life," by Professor Ebstein; and "Edward Jenner and the Immunity Question," by Professor Ackermann.

The British Pharmaceutical Conference held its annual meeting in Cardiff, August 17th, 18th, and 19th, under the presidency of Mr. Martindale, of London.

Female Medical Students in India.—Lady Dufferin's scheme of educating women for the practice of medicine among the native women, who would never be permitted to receive a male physician, is now in active operation. There are twenty-six students under training in the Madras Medical College, of which number six are being trained for the Hospital Assistant's grade, and the rest for the Apothecary's grade. Six of these students, three in each grade, are expected to graduate in a short time.

A Letter from Dr. Holmes.—The following letter from Oliver Wendell Holmes, to the editor of the *Australasian Medical Gazette*, acknowledging the receipt of some papers relating to the practice of medicine and surgery in New South Wales, appears in a recent issue of that journal:

"BOSTON, April 25, 1891.

"MY DEAR SIR: I thank you most cordially for the very important and interesting papers relating to quackery as it appears in your great colony. Although it is a very long time since I have practised medicine, I retain my interest in all matters relating to the profession, and am glad to add these valuable documents to my library, for the present, but to go eventually with the rest of my medical books, which I gave some years ago to the Boston Medical Library.

"Believe me, dear Sir,

"Very truly and gratefully yours,

"OLIVER WENDELL HOLMES.

"THE HON. JOHN M. CREED, Sydney."

American Association for the Advancement of Science.—At the meeting of this Association, held in Washington August 19th to 25th, there was a dearth of papers possessing any strictly medical interest; for out of some two hundred and fifty papers read before the eight sections, only the following seem to deserve mention here: Dr. Theobald Smith, of Washington, read a paper before the Biological Section on "Uses of the Fermentation-tube in Bacteriology," with demonstrations. The fermentation-tube was applied to bacteriological work by Miquel, in 1889, and independently by Dr. Smith at about the same time. The object of the speaker was to call attention to its value in the differentiation of closely allied species or varieties of bacteria, in the preliminary study of gas production, and in the cultivation of anaërobic forms. It was also useful in demonstrating in the class room the very active metabolism of bacteria. Experiments with the tube showed that the bacteria of typhoid do not cause an evolution of gas. Professor Joseph Jastrow described tests he had made with a young man who had been born without the sense of smell. The object of the tests was to find out just what things are really tasted in eating, and what are only perceived through olfaction. The committee of the Chemical Section on spelling and pronunciation of chemical terms, made their final report, which will be printed and distributed to chemical laboratories throughout the country. Professor L. P. Kinnicutt read a paper before the Chemical Section entitled "The Purification of Worcester Sewage by Chemical Precipitation." The sewage of Worcester contains a large quantity of the waste products of various manufacturing establishments, and an unusually large amount of free acids and iron salts. The method in use for the purification of the sewage is the one known as the Carpenter process. Lime is added until the sewage is just alkaline, and by this process all the suspended matter in the sewage is removed and the total organic matter is reduced over two-thirds. The effluent is clear and colorless, without odor, and, though by no means drinking-water, can cause no nuisance when run into a stream whose volume is not over five times that of the effluent. Dr. Walter Maxwell read a paper on "Biological Functions of the Lecithines." In a paper presented by Mr. Maxwell at the 1890 meeting of the Association, he showed that a vegetable organism, during the initial stages of growth and under the action of the ferments operating in germination, possesses the power of taking the phosphorus present in seeds or in soils as mineral phosphates, separating the phosphorus from the inorganic combination and causing it to reappear in the young plant, but in an organic form as a lecithine. In this second paper he showed that the lecithine bodies, on the other hand, present in the animal kingdom revert to the mineral form under the action of the ferments present in the animal organism. The investigations of Mr. Maxwell have therefore shown that the lecithine bodies are a medium through which phosphorus conducts its circulation between the three great kingdoms of nature, passing from the mineral, through the vegetable, into the animal kingdom, where it reappears as a mineral compound. The attendance of members was larger than at any other meeting for several years, notwithstanding the heat. Professor Joseph Le Conte, of California, was elected President, and Rochester, N. Y., was selected for the meeting next year.

Public Baths in New York.—The Association for Improving the Condition of the Poor has erected a building on Centre Market Place, in this city, in which anyone in need of a bath can wash and be clean. There are twenty-five bath-rooms in the building, and one thousand people can be accommodated there each day. The charge for a bath, including a new cake of soap and the use of a large crash towel, is only five cents, and free baths are given to those who cannot afford to pay this small sum. The new bathing establishment is the result of a movement started some years ago, at the instance of Dr. Baruch, Chairman of the Committee on Hygiene of the County Medical Society. The Demilt Dispensary also offers facilities to the poor in bathing, having within a few days set up seven bath-rooms in the basement of its building on Twenty-third Street. The fee for a bath is here ten cents, but this charge is remitted if the applicant is unable to pay. If this experiment proves a success the trustees of the dispensary propose to convert the entire basement into a bath-house, there being room there for forty or more rooms.

The Health of the Pope.—A correspondent writes from Italy to *The Lancet*, concerning the reported grave illness of the Pope, as follows: "Leo XIII. is an octogenarian, who leads a busy life, sometimes, indeed, so very busy that his strength is hardly equal to the strain imposed on it. On these occasions there is generally a recrudescence of two chronic ailments—to wit, intestinal catarrh, with sympathetic response of the renal organs. Moreover, with advancing years, he has betrayed something like the initial stages of senile anæmia. These symptoms concurring after an unusual press of business are apt to terminate in considerable prostration of the bodily powers, the mind remaining clear and active; and this prostration is, in turn, followed by extreme, sometimes alarming, somnolence. From this, however, his Holiness always emerges with renewed strength, and a general abatement of the complications, to resume his learned labors and meet the demands, administrative or diplomatic, of his post. His health is carefully and skilfully watched by physicians devoted to his service."

International Dermatological Congress.—The second meeting of this society will be held in Leipsic on September 17th, 18th, and 19th.

Vaccination Statistics.—In Riga, a city of 180,000 inhabitants, there were some 6,500 belonging to a religious sect living by themselves in a certain quarter of the town. These people opposed the practice of vaccination on conscientious grounds. Between the years 1882 and 1887 the average mortality from small-pox in the city was 108 annually. From December, 1886, to the end of March, 1887, about four months, there were 155 deaths from this cause, owing to a slight epidemic during that period. Of this number 71 occurred among the orthodox population, equal to 109 per 10,000, while the deaths among the remaining inhabitants only numbered 84, equal to 4.8 per 10,000. Down to the year 1887, as stated above, the average number of deaths annually from small-pox was 108. After this epidemic vaccination and re-vaccination were largely enforced, with the result that from 108 the annual number of deaths due to this disease fell at once to 8.

Dr. C. L. Gummert, of Brownsville, Pa., died recently at his home, of pulmonary phthisis. He was treated last winter in Berlin by the Koch method, but derived no material benefit from it. He was a member of the Pennsylvania State Board of Health.

Yellow Fever in New York.—Several suspicious cases of fever have occurred in and around this city in the past few days, the sufferers having been passengers on the steamer Santiago, which arrived from Cuba on August 21st. Investigation by the health authorities has shown that the disease was a pernicious remittent and not yellow fever. That it was not the latter is fortunate. At least six of the passengers on the steamer are now known to have been sick on the day of their arrival in this port, yet the vessel seems to have passed through Quarantine without any detention. While it is possible that the medical officers may have been a little less careful than they should, yet they may not be in the least degree responsible, as it would be a comparatively easy matter for the fact of a man's being ill to escape the eye of the inspector as long as the patient was able to be on deck. But this occurrence emphasizes the necessity of having surgeons on passenger steamships running to the tropics, a matter brought up by the Health Officer in his last annual report and referred to recently in these columns. A surgeon on the steamer during the six days' voyage from Cuba would have had time to examine these cases carefully and to make a rational diagnosis. He would have reported them to the medical officers at Quarantine, the liability of an error in the diagnosis would have been reduced to a minimum, and a good many timid people would have been spared the shock of a yellow-fever scare.

Rabies in Austria.—The Austrian health authorities have been collecting statistics in regard to hydrophobia in that country. They have ascertained that the number of dogs attacked by the disease is from 700 to 800 annually. The number of persons annually attacked by dogs thus infected is from 250 to 430, showing a total of 3,021 cases during the past ten years. The deaths during this period numbered 822.

One Hundred and Eight Years Old.—Mr. Jacob Steel, who died at a small town near Pittsburg, Pa., on August 24th, was born in Fayette County, in that State, on October 19, 1783, and would consequently have been one hundred and eight years old had he lived eight weeks longer. He used to say that he remembered distinctly the day of Washington's second election to the Presidency, and his first vote was cast for Jefferson. His habits were simple, he was rather careful in his diet, drank a little whiskey occasionally, but never used tobacco. What probably contributed as much as anything else to the prolongation of his life, was a cheerful disposition and a remarkable evenness of temper.

Contaminated Croton Water.—The chemist to the Health Board has found in a number of recent analyses of the water supplied to this city traces of nitrites, presumptive evidence of sewage contamination. And unfortunately an inspection of the Croton water-shed bears out this evidence of contamination furnished by chemical analysis. Drains from slaughter houses, factories, barns, cemeteries, and dwelling-houses are found emptying into the streams that feed our water-supply, and the wonder only is that a dangerously foul condition has not been reached before.

Arsenic Poisoning from Coal.—A source of contamination with arsenic recently pointed out is from coal. When coal is burnt it is roasted out and it is the only product of the coal which is at first volatile, and afterward non-volatile. A part of the smoke that goes into the air is arsenious acid mixed with carbon, and a large part of it lodges in the chimneys. Now take a city like London, or any of the great English cities where coal is burnt very freely, there the quantity of arsenious acid that is given into the air must be very considerable, and it would be interesting to make comparative tests of the urine of persons in a city like Boston and in a city like London. The English coal is very bad coal in this respect. Every ton of coal burns off about twenty to forty pounds of sulphur. That sulphur is transformed into sixty pounds of sulphuric acid, which has left its stain on every marble building in London. I speak of the sulphur because the sulphur is largely accompanied by arsenic.—Professor Crafts in *Boston Medical and Surgical Journal.*

American Surgical Association.—The following is the programme of the annual meeting of this Association, to be held in Washington, September 22, 23, 24, and 25, 1891. 1. "Present Status of Brain Surgery," by Dr. D. Hayes Agnew, of Philadelphia. Discussion by Mr. John Chiene, of Edinburgh, Scotland, Dr. W. W. Keen, of Philadelphia, Pa., Dr. C. B. Nancrede, of Ann Arbor, Mich., Dr. Roswell Park, of Buffalo, N. Y. 2. "Report of the Committee on the Results which Should be Considered as Satisfactory, of Treatment of Fractures of the Shaft of the Femur," by Dr. Stephen Smith, of New York. 3. "Aseptic and Antiseptic Details in Operative Surgery," by Dr. A. G. Gerster, of New York. Discussion to be opened by Dr. Robert F. Weir, of New York. Dr. J. Collins Warren, of Boston, Mass., Dr. J. William White, of Philadelphia, Pa., Dr. Joseph Ransohoff, of Cincinnati, O. 4. "Surgical Treatment of Injuries and Diseases of the Vertebral Column," by Dr. J. William White, of Philadelphia, Pa. Discussion: Dr. Maurice H. Richardson, of Boston, Mass., Dr. H. H. Mudd, of St. Louis, Mo., Dr. John B. Roberts, of Philadelphia, Pa., Dr. Charles B. Porter, of Boston, Mass., Dr. Robert Abbe, of New York, Dr. W. W. Keen, of Philadelphia. 5. "On Retro peritoneal Abdominal Tumors, and Especially those Involving the Kidney," by Dr. A. Vander Veer, of Albany, N. Y. Discussion: Mr. Reginald Harrison, of London, England, Dr. Robert Abbe, of New York, Dr. William T. Bull, of New York, Dr. Frederick E. Lange, of New York. 6. "Recurrence of Cancer of the Breast," by Dr. Frederic S. Dennis, of New York. Discussion: Mr. Thomas Bryant, of London, England, Dr. Hunter McGuire, of Richmond, Va., Dr. Lewis S. Pilcher, of Brooklyn, N. Y., Dr. D. Hayes Agnew, of Philadelphia, Pa., Dr. L. McLane Tiffany, of Baltimore, Md. 7. "The Treatment of Tuberculosis of Bones and Joints by Parenchymatous and Intra-articular Injections," by Dr. Nicholas Senn, of Milwaukee, Wis. Discussion: Dr. Lewis A. Stimson, of New York, Dr. John Ashhurst, Jr., of Philadelphia, Pa., Dr. Frederick E. Lange, of New York, Dr. A. G. Gerster, of New York, Dr. A. T. Cabot, of Boston, Mass., Dr. D. D. Bramble, of Cincinnati, O. 8. Treatment of Fractures Involving the Elbow joint," by Dr. Lewis A. Stimson, of New York. Discussion: Mr. Arthur Edward Durham, of London, England, Dr. D. Hayes Agnew, of Philadelphia, Pa., Dr. N. P. Dandridge, of Cincinnati, O., Dr. R. A. Kinloch, of Charleston, S. C., Dr. D. W. Yandell, of Louisville, Ky., Dr. Stephen Smith, of New York City, Dr. E. M. Moore, of Rochester, N. Y., Dr. James McCann, of Pittsburg, Pa.

In addition to the above the following papers are offered and will be read as opportunity offers at the end of each day's programme: "Fractures Involving Upper Third of Femur, Exclusive of Neck," by Dr. Oscar H. Allis, of Philadelphia, Pa.; "Thoracic Surgery," by Dr. De Forest Willard, of Philadelphia, Pa.; "A Case of Diffuse Hypertrophy of the Breasts, with Photographs," by Dr. C. B. Porter, of Boston, Mass.; "Fractures of the Bones which Form the Elbow-joint and Their Treatment," by Dr. Levi C. Lane, of San Francisco, Cal.; "Old Unreduced Luxations of Elbow," by Dr. Lewis A Stimson, of New York; "The Study of a Case of Hemiplegia with Aphasia, Following Ligature of Common Carotid Artery," by Dr. J. Ewing Mears, of Philadelphia, Pa.; "Investigation of Pistol-shot Wounds of the Skull, and their Treatment," by Dr. E. H. Bradford, Boston, Mass.; "The Result of Some Experiments in the Filling of Cavities in Bones Following Operations for Caries," by Dr. E. H. Bradford, Boston, Mass.

Liebreich's Cantharidin.—In a letter to the *University Medical Magazine*, Dr. Walter F. Atlee, of Philadelphia, after alluding to the well-known fact that lanolin is nothing new, having been familiar to Pliny, remarks that the same ancient author spoke of various preparations of cantharis being used for the same purpose for which Dr. Liebreich has brought his cantharidin forward. Dr. Atlee conjectures that we may soon hear of ovin, inasmuch as Pliny extolled the efficacy of eggs in erysipelas, burns, and pimples.

Typhoid Fever is prevailing to an unusual extent in Newark, N. J., as many as eight and ten new cases of the disease being reported to the Health Board every day. The city's water supply has been the subject of many complaints for some time past.

A Supporter of the New Code a Trustee of the American Medical Association.—The three new members of the Board of Trustees elected at Chicago were Dr. William Warren Potter, of Buffalo, N. Y.; Dr. W. W. Dawson, of Cincinnati; and Dr. John H. Rauch, of Chicago. A silly but futile effort was made to prevent Dr. Potter serving as a member of the Board of Trustees, the charge being made that he was ineligible on account of his membership in the New York State Medical Society, the Society which modified the Code a few years ago; but inasmuch as Dr. Potter has been for sixteen years a member of the American Medical Association, with dues constantly paid up, was last year elected President of the Gynecological Section, and has had a paper to read before the Association every year for a good many years, and is a member in good standing of the Erie County Medical Society, a splendid Society and one directly in line with the American Medical Association, the charge of being unethical could not stand.—*Medical Mirror.*

A New Disease of Americans.—According to Dr. Lange, perityphlitis, or appendicitis, is unusually common in America, and particularly in New York, one surgeon, for example, having encountered twenty-one cases in a period of eleven months. This Dr. Lange attributes to two of our national failings, that of eating too much and chewing too little, the result of which is constipation. Contributory causes of the prevalent constipation are our hurrying, restless, nerve-straining lives, which lead us to ignore the demands of nature. Fecal accumulation sets up trouble in the mucous membrane of the cæcum. So-called fecal calculi are often found, but very rarely—much more rarely than was formerly believed—foreign bodies, as causes of appendicular disease. The presence of pent-up secretions in the appendix is prone to set up an inflammatory condition, and this may pursue its course without destroying the integrity of the appendicular wall, or it may lead to extra-cæcal suppuration, which is almost always situated within the peritoneum, rarely between the layers of the meso-colon, and almost invariably accompanied with perforation of the appendix.

Reviews and Notices of Books.

TEXT-BOOK OF BACTERIOLOGY. By CARL FRAENKEL, M.D., Professor of Hygiene, University of Königsberg. Third edition, translated and edited by J. H. LINSLEY, M.D., Professor of Pathology and Bacteriology, Medical Department of the University of Vermont; Demonstrator of Pathology and Bacteriology, New York Post-Graduate Medical School and Hospital, Pathologist to the New York Post-Graduate Hospital and the New York Infant Asylum. Pp. 376. New York: William Wood & Co.

THIS book will receive, and deserves, a warm welcome, not only for its intrinsic merit, but because it supplies a decided want in English medical literature. Heretofore there has been no English text-book on bacteriology; now we have what is probably the very best published. It not only takes a first rank in Germany, but has been translated and published in six different languages. The author in his preface "does not claim complete, or exhaustive, discussion of the subject, and presents no statements from literature; only such facts and observations have been given as were examined by myself." A careful reading almost disproves this statement, as the book is remarkably complete for one of its scope. It is all a beginner could desire, and is a perfect manual for the most advanced bacteriologist. The first chapter is devoted to a classification and description of bacteria. It is excellent in every particular. The two succeeding chapters are the most valuable in the book, relating as they do to "Methods of Investigation," and "Methods of Breeding." The former includes the preparation of stains, and the details of all methods of staining. The directions are clear and simple, and no one following them need have failure. In the chapter on breeding, the author tells how to prepare the various culture media, and, what is still more valuable, how to properly use them. The remainder of the book is devoted to the description of the various kinds of bacteria, both pathogenic and non-pathogenic, investigation of air, soil, and water, and mold, and yeast fungi. The author is a devoted follower of Dr. Koch, and the latter's teachings are seen on every page. The translation is an excellent one, Dr. Linsley's English being clear and forcible. The lecture style of the original is changed very advantageously into the ordinary form; the first edition of the English version will doubtless have a ready sale, and it is to be hoped that in succeeding editions illustrations will be added.

MEDICAL PUBLICATIONS OF THE HARVARD MEDICAL SCHOOL. Vol. III.

THIS is a handsome book, containing eighteen articles by the Faculty of the Harvard Medical School, presented in this form to show the character of the original work done in the school. H. P. Bowditch contributes two excellent essays on the knee-jerk, and one on the physique of Massachusetts women. J. Armory Jeffries gives the results of his experiments with the sterilization of milk and food for infants, and also on the anti-bacterial action of iodoform. Thomas Dwight writes on the sternum as an index of sex, height, and age, and on the closure of the cranial sutures as a sign of age. There are other equally valuable papers by Drs. Bullard, Brackett, Lovett, Luce, Bryant, Hooper, Pease, Ernst, and Warren.

EXPERIMENTAL INVESTIGATIONS BY THE STATE BOARD OF HEALTH OF MASSACHUSETTS. 1888–90. Illustrated. Pp. 910. Boston: Wright & Potter Printing Co.

THIS is Part II. of the Report on Water Supply and Sewage, and its contents are as follows: "Purification of Sewage by Filtration and by Chemical Precipitation," by HIRAM F. MILLS, A.M., C.E.; "A Report of the Chemical Work of the Lawrence Experiment Station, Including Methods of Analysis, and some Investigations of the Process of Nitrification," by THOMAS M. DROWN, M.D., and ALLEN HAZEN; "Report of Experiments upon the Chemical Precipitation of Sewage," by ALLEN HAZEN; "Report of the Biological Work of the Lawrence Experiment Station," by WILLIAM T. SEDGWICK, Ph.D.; "Investigations upon Nitrification and the Nitrifying Organism," by E. O. JORDAN and ELLEN H. RICHARDS. There are twenty excellent diagrams and plates.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Vol. III. Third session, held at Atlanta, Ga., November 11, 12, and 13, 1890. Pp. 444. Published by the Association.

THE Southern Surgical and Gynecological Association is doing a great work in the South. It is but three years old, but in that short time its membership has reached one hundred, and includes some of the most distinguished and learned men in the profession. The meetings are well attended, and not only tend to elevate the profession in the South, but have a marked influence on the entire profession. The papers are always of unusual excellence, and those in the work under review are no exception to the rule. There are thirty-two of them, relating to all the subjects that are most prominently before surgeons and gynecologists. They make up a book that is of value to every professional man. It is handsomely bound in cloth with gilt top. The Secretary, Dr. W. E. B. Davis, of Birmingham, Ala., deserves credit for the excellent manner in which he has compiled and published the book.

"JOE BROWN," DOCTOR, ON ALCOHOLISM, ITS CAUSE AND CURE. Pp. 105. New York: E. Scott, Publisher.

THIS is an excellent and very readable little monograph, written by a doctor who not only became a victim of the alcoholic habit himself, but also had the opportunity of studying it in all its phases in a number of institutions devoted to the care of inebriates. The book is handsomely bound in buff leatherette with gilt top. It is adapted to the general as well as the professional reader.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Vol. IX., No. 1, July, 1891. Contents: "Hay Fever and Paroxysmal Sneezing," by SIR MORELL MACKENZIE, M.D. "Tuberculosis of the Bones and Joints," by DR. FEDOR KRAUSE. "A Study of Malignant Disease of the Upper Air-Tract," by FRANCKE H. BOSWORTH, M.D.

THE first of the three monographs, that on "Hay Fever," by Sir Morell Mackenzie, appears at an opportune time, when the sufferers from this most trying of affections are appealing once more to their medical advisers and then, for the most part, despairingly leaving them and seeking relief, though not cure, in the mountains. The essay is complete and written in the author's most pleasing style. Dr. Krause's essay contains much of original pathological work on joint tuberculosis, and a careful consideration of all that bears upon it, which has been so fully written in German and so scantily in English. The paper is illustrated by forty-three cuts, and several lithographic plates. Dr. Bosworth's short paper, which closes this number, is an excellent presentation of a subject of much interest, concerning which not a very great deal has been written.

The Climate of Western Washington.—An observer at Port Blakely, Wash., reports that the hottest day in that place, in a period of fourteen years, was June 6, 1878, when the temperature record was as follows: morning, 62°; noon, 94°; evening, 73°. Since then on only three has a record of 92° been made. The lowest temperature days recorded was on the morning of January 15, 1888, 3° above zero, the next lowest being on February 11, 1884, 7° above zero. There has not been sufficient frost in the fourteen years to destroy potatoes left in the ground where they grew.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, May 19, 1891.

FRANCIS DELAFIELD, M.D., CHAIRMAN.

Pulmonary Syphilis in the Adult.—DR. THOMAS E. SATTERTHWAITE read a paper on this subject. His reason for presenting the subject at the present time, he said, was because he had some personal experience which he thought would contribute toward the solution of this vexed question. That there were two sides to it was very evident, since many authorities, past and present, did not believe in the existence of pulmonary syphilis at all. Furthermore, he was confident that the majority of general practitioners to-day would affirm that they had never met with this affection. Laënnec and Andral made no allusion to it, and Hunter, Ricord, Bayle, Fagge, and other standard authorities denied its existence or expressed their doubt in regard to it. The negative side had also derived at times strength from pathologists. Thus, Virchow in his early career found himself at a loss for criteria in distinguishing pulmonary tuberculosis from syphilitic phthisis, and Ziegler, in his recent work (1887), followed in the wake of these early views. But neither of these men would be willing to affirm that syphilis of the lungs does not exist; but rather that there were at present grave difficulties in the way of a positive diagnosis from post-mortem appearances.

The difficulties were undoubtedly great, but whether they were insurmountable or not was the question to be determined. In support of the positive position on this matter, it might be said, first, that the greatest of all the early pathologists, Morgagni, described lung syphilis in his epistles (1806), intimating that Valsalva was the real discoverer of the disease, about one hundred years earlier. The next decided step in advance was made when De Paul, in 1837, described a peculiar fibroid induration of the lungs in the congenital syphilis of infants. Following out this same line of observation, he found a somewhat similar condition in two adult patients, where the lungs, on post-mortem examination, were seen to have "purulent foci-bronci-ectasis and purulent infiltrations." From this time on the French observers, and notably Lagneau (1851), did much to solve the question before us.

Mode of Action of Syphilis upon the Lungs.—From an analysis of fifty-three cases the latter found that the syphilis might act on the lungs and bronchi in two ways, as follows:

1st. By producing changes essentially syphilitic in their character and divisible into two classes:

1. Affections which are generally slight, consisting of acute inflammation of the bronchi and parenchyma of the lungs, extensive inflammation of the bronchi, asthma, and chronic inflammation of the bronchi.

2. Serious affections which are described by most authors under the head of phthisis, comprising ulcerous chronic inflammation of the parenchyma of the lungs and the lymphatic ganglia, inflammation of the pleura, and syphilitic tubercle (miliary or gummy deposits).

2d. By aggravating and hastening the development of pre-existing disposition to tubercle.

In England Munk followed De Paul, giving a satisfactory review of the subject; but it was reserved for Stokes (1844) to furnish us with certain definite clinical signs. In describing a case of supposed phthisis he said: "See whether there is any syphilitic taint, and if so, examine for periostitis of the chest." He observed that secondary syphilis resembled phthisis, and exhibited a peculiar bronchial irritation; furthermore, that with a large amount of pulmonary tissue involved, the clinical signs were comparatively few. Graves, following in 1848, upheld these views, and based his diagnosis on the success of anti-syphilitic remedies when the patient had the physical signs of (tubercular) phthisis.

In 1852 Weber described the pathological aspect of the consolidated lung under the term "white hepatization," a phrase that later led to the name "white pneumonia," by which the fibroid lung of syphilis was now known among pathologists. To the practised eye there was something fairly distinctive in this white pneumonia; so that one could almost see at a glance, on post mortem examination, that we had a syphilitic lung. It was best seen in the earliest or middle stages of infiltration.

Diagnosis of Pulmonary Syphilis.—Having alluded to other German writers and to Moxon's analysis of cases in the "Guy's Hospital Reports" for 1868, Dr. Satterthwaite said that Walshe, in his well-known work on diseases of the lungs (1871), expressed the opinion that the diagnosis could be made in pulmonary syphilis, by noting the disproportion between the physical signs and the severity of the malady; by a unilateral bronchitis, by either the slight character of the night-sweats or their absence; and by the result of specific remedies. In 1877 Greenfield mentioned among the clinical signs a decided tendency to profuse hæmoptysis, which he attributed to the great vascularity of the new connective tissue. Such an explanation would, of course, only apply to the formative stage of the fibroid induration of the lungs.

In this country we had had excellent matter from Van Buren and Hayes, Bumstead and Taylor, Hyde and Bruen; while Porter had laid down rules for positive diagnosis which had attracted general attention. The latter laid stress on the following physical signs: Dyspnœa on inspiration, a varying degree of supra- and sub clavicular retraction; on percussion, marked dulness over the affected parts; on auscultation, prolonged and high-pitched inspiratory murmur, with a decided interruption or pause between it and the expiratory murmur, which is prolonged and high pitched. The pitch is higher in inspiration and expiration than in emphysema. There is almost total absence of sibilant or sonorous râles, also of the crepitant and subcrepitant; and very pronounced vocal fremitus on counting. He regarded this peculiar respiration without râles, with abundant sputum, together with a marked tenderness over the sternum, as almost pathognomonic of pulmonary syphilis. Dr. Porter, as almost all writers, limited their points of differential diagnosis to the condition of fibroid induration where there were no appreciable cavities. Such a case, from the practice of Dr. Zeh, he had seen quite recently with Dr. Porter. The diagnosis of syphilitic phthisis, made before death, was strengthened at post-mortem examination by the general signs of visceral syphilis in the lungs and liver; while a subsequent microscopic examination of the diseased lung-tissue failed to disclose any tubercle bacilli.

Pathology.—Dr. Satterthwaite then went on to speak more particularly of the pathological evidence supporting the theory of syphilitic phthisis.

1. He said we often found in the lung a peculiar tumor known as "the gummy," small, yellowish in color, sticky to the feel, and sharply defined from the surrounding tissue. It was a recognized lesion of tertiary syphilis, forming one of the most common deposits in the liver or kidneys, and was more prominent in the middle or lower lobes of the lungs than elsewhere.

2. In another class of cases we had appearances simulating those of miliary tuberculosis, but without the so-called tuberculous bacilli.

3. In another class we had the peculiar fibroid induration previously mentioned. It was presumably an advanced stage of the miliary formation, and was the most characteristic of the syphilitic lesions. At first the indurated fibrous tissue had a pellucid bluish appearance, but later on was white and glistening.

4. If the miliary deposits aggregated and softened (as would be the case if the treatment were unsuccessful)

cavities, which were usually small, would form, and be found first in the apices, just as in tubercular phthisis.

5. Associated with these intra-pulmonary changes there was an unusual amount of fibrous pleurisy, and pleuritic effusions were also comparatively frequent.

While there were none of these lesions, except the gummy tumor, that were positively determinable at the post-mortem table, yet, in conjunction with the patient's history, the physical signs, and the microscopic examination of the sputum or of lung-tissue after death, the diagnosis might be made with a remarkable degree of certainty.

There was no doubt that lung syphilis was comparatively uncommon, and Dr. Satterthwaite's observations in the main agreed with those of Greenfield and Goodhart on this point. In 95 patients that came to the post-mortem table with supposed tubercular phthisis, 12 had evidences of syphilis in their lungs (thirteen per cent.). Of these 12 cases, 6 were selected as pure examples of syphilitic phthisis (six per cent.). In the remaining 6 cases it was possible, and indeed probable, that tubercular phthisis was a concurrent lesion (six per cent.). Hence, it would appear that syphilis of the lungs was quite as often associated with tubercular phthisis as that it was the single lesion. Having given the statistics of his clinical records at the Post-Graduate School in reference to phthisis, constitutional syphilis, and lung syphilis, he proceeded to compare the two sets of phthisical cases (which happened to be exactly equal in number) together. Of the 95 phthisical cases that came to the post-mortem table in his hospital practice, 12 had lung syphilis, or 12.6 per cent., while of the 95 phthisical that came to his clinic, 14 were put down as having lung syphilis, or 14.7 per cent., a difference of only from two to three per cent.

That syphilis might play an important part in inherited phthisis he felt assured from personal experience at the bedside; but the exact relation between the two had yet to be established. It was apparent, however, that a man suffering from a severe form of progressive syphilis, and who became in consequence greatly deteriorated in health, was a fit subject for the development of tuberculosis if other conditions favored. In such persons the two diseases might develop side by side, each intensifying the other. Again, from a pathological point of view, in the early stages of both diseases there were the same catarrhal features, and in the further progress of the disease the same tendency to thickening and degeneration of vessels, implication of lymphatics, and the production (in certain types) of an imperfect form of fibroid tissue, much as in fibroid tuberculosis. As to the microscopic character of the tubercle, so good an observer as Goodhart failed to find any difference between them, and others had sustained this view.

Symptoms.—In pulmonary syphilis he had found rapid breathing and dyspnœa quite common; but it was notorious that we might not be able to detect the cause of the trouble either by auscultation or percussion, although, judging from post-mortem records, it was proper to suppose that a certain amount of deposit had taken place which the ear could not detect. Cough was an early symptom. Expectoration was slight at first, but in advanced cases copious. Hæmoptysis and night-sweats he believed to be uncommon. Even in advanced cases emaciation was infrequent, and this symptom contrasted strongly with fibroid tuberculosis. The temperature rarely exceeded 101° F., in this respect also contrasting strongly with tuberculous patients. When there was a wide dissemination of syphilitic tubercles, or when there were small, gummy tumors, auscultation and percussion might fail to reveal anything; but so soon as fibroid induration had commenced we would be likely to have the signs of beginning consolidation. It was generally supposed that syphilis elects by preference the middle and lower lobes of the lungs; and this was true of gummy tumors, but not of the miliary deposits, or of the induration. When the disease had advanced to the point where there were evidences of destructive changes, there was usually copious albuminuria and casts of all kinds, with uræmic symptoms. At this point, too, we were apt to have some suggestive signs of brain implications. Many of the criteria that had been given by writers for determining this disease related not to it, but to its concomitant lesions. Thus, nervous phenomena related to cerebral syphilitic lesions, and periostitis was simply a common manifestation of constitutional syphilis.

Treatment.—After some remarks in regard to the differential diagnosis, Dr. Satterthwaite said he was a firm believer that syphilis is a disease not only amenable to treatment in all stages, but capable of being arrested and held in check in almost all cases, at any time before destructive changes have taken place. As in tubercular phthisis, we could not restore a tissue that had become neurotic, but even then elimination of the morbid products and cicatrization were still possible. Hence, up to the stage of softening specific remedies, actively pushed, would act promptly and well. The paper concluded with the narration of the six cases of pure syphilis of the lungs referred to in which an autopsy was made.

Dr. Robert W. Taylor said, that when Dr. W. H. Porter read his paper some years ago, and he heard the views expressed by Drs. Delafield and Draper, he found himself in a state of considerable doubt and uncertainty on this subject. He therefore resolved to make a careful study of all cases coming within his knowledge that seemed to have any bearing on it. In this connection he would say that in an article by Lancereaux, published in the *Union Médicale* for January, 1891, that author took the ground that it is very difficult to distinguish, even with the microscope, between syphilis of the lungs and tuberculous disease, and that the two may go hand in hand together. He recognized two forms of pulmonary syphilis. In the first, there was a proliferation of connective tissue around the smaller blood vessels, which later resulted in fibroid consolidation of the lung. In the second, the lesion consisted of a growing tumor.

Dr. Taylor said that he had seen cases in which pulmonary tuberculosis supervened upon syphilis. One very interesting case he had previously reported, where the patient, suffering from a severe papular syphilide, was supposed to have small-pox, and later developed tuberculosis and died. At the autopsy the physician making the examination became infected with syphilis from a cut; and this was one of the cases on record in which inoculation took place from a cadaver. He had gone over his records of cases to see what light they would throw on this subject of pulmonary syphilis, and would relate four of them by way of illustration. These cases he gave as follows:

Case I.—A gentleman, thirty-two years of age, in fine health, contracted syphilis early in 1888. He had general exanthemata and mucous lesions, and followed treatment for perhaps six months. He came to me in May, 1890, rather more than two years after infection, having an obstinate syphilitic psoriasis. At this time he was pale and thin, and complained of a slight hacking-cough and of pain on breathing over a patch having an area of three square inches on his side, over the middle lobe of the left lung. He expectorated a little mucus, mostly in the morning. Over the morbid area there was very slight dulness, and rough breathing could be heard. There was no elevation of temperature. He was put upon mixed treatment and syrup of iodide of iron. Within a month his pain ceased, he coughed less, and he gained strength. In July he weighed more than he ever did in his life, and felt correspondingly well. At this time there was no perceptible lung trouble.

Case II.—A gentleman, twenty-two years of age, syphilitic for eighteen months, but had taken no treatment until one year after infection. In May, 1890, he first noticed shortness of breath and a slight cough. Sputum not very copious, mucoid, a little fetid, and occasionally

streaked with blood. A physical examination showed dulness over the left side, about the middle of the lower lobe; its area being the size of a lemon. During inspiration, large and small râles were heard. He was thin, pale, and sallow, and very weak. Under the mixed treatment and iodide of iron he was seemingly entirely cured in July of the same year. Promptly after the beginning of the treatment he began to feel better, and quite rapidly his nutrition became improved; so that he regained his color and flesh. In July, Dr. Taylor could not find any abnormalities in the lung. There was at no time any elevation of temperature, though in May the pulse was thin and rapid.

Case III.—A married woman, aged thirty-eight, a blonde of poor fibre, infected with syphilis in October, 1886, came to Charity Hospital in 1887, giving a history of mucous patches in the mouth and vulva, syphilitic rheumatism, and a great falling away in flesh and strength. She was treated energetically, but remained in the hospital only one month. In July, 1887, she came back with diffuse gummatous infiltrations in the fingers, and over the body. She was patched up again, and as soon as her lesions healed she went out. In November of the same year she came back again with the following story, and the following condition: For a month previously she had had a slight cough, was a little short of breath upon exertion, and noticed that she was more readily fatigued than before. She had not followed the directions given her on leaving the hospital in July, to keep on with medicine, and get all the fresh air she could. Being a dressmaker, and the mother of children, she had had to apply herself to the needle for long hours each day. In this state, and under such conditions, she had been taken, two weeks before coming in, early one morning, with an alarming hemorrhage (the blood being very dark and thick), which continued free for about an hour, and then kept up in a mild degree all the day. Her general symptoms became worse, and she had three other hemorrhages of less severity before her admission to the hospital.

Examination showed very slight elevation of temperature (this being more marked in the evening than in the morning), and general prostration. Over the upper lobe of the left lung, extending three inches down from the clavicle and all the way across the chest, there was marked dulness on percussion, and on auscultation there was heard a whistling noise, mixed with moist râles. Everywhere else the lungs were normal. The woman was put on extra diet, sent out daily in the warm part of the day, was given the strong mixed treatment, the chest being rubbed every evening with twenty grains of strong mercurial ointment, and was sent home with no appreciable trouble in her lungs, and in a fair state as to flesh and strength, in the middle of January, 1888.

Case IV.—In August, 1890, Dr. Taylor was asked to see in consultation a man twenty-five years of age, thin, pallid, and wan, who had been affected with syphilis in June of that year. He had at the date of examination double syphilitic hydro-arthritis of the knee-joints. He had been treated with mercury, but had borne it badly. In September he had inflammation of the left ankle-joint, and complained of weakness, night-sweats, and great dyspnœa. In spite of the best care, he became rapidly worse, and in November there was evidence of diffuse infiltration in both lungs. He continued to fail very fast, and died early in December.

From a study of these and other cases, Dr. Taylor said that he had arrived at the following conclusions:

1. That syphilis predisposes to tuberculosis; and 2. that there are certain clinical manifestations which depend on the morbid changes that are produced in the lungs by syphilis.

Dr. Satterthwaite then read a letter in regard to pulmonary syphilis which he had received from Professor William H. Welch, of the Johns Hopkins University, Baltimore.

Dr. Welch thought that the subject of syphilitic lesions in the lung was still in a state of confusion, and was not very likely to be thoroughly cleared up before we possessed, by the detection of the specific germ of syphilis, as positive a means of recognition of syphilitic lesions as we had in the tubercle bacillus for tuberculosis. Unquestionably, a large proportion of the cases of pulmonary syphilis reported in the adult had been cases of tuberculosis. Some writers seemed to suppose that by demonstrating the existence of syphilis in the patient they had brought sufficient evidence that the coincident pulmonary disease was of a syphilitic nature. Neither the existence of syphilitic infection nor improvement or cure of the pulmonary affection by antisyphilitic treatment seemed to him satisfactory proof that the alteration in the lung was syphilitic. In the present unsettled state of the question a case reported clinically, without any post-mortem examination, was valueless as to the establishment of specific pulmonary syphilitic lesion. It was curious to find that even in recent years cases had been reported as syphilis of the lung on the basis of the clinical history, even without examination of the sputum for tubercle bacilli, as well as on the basis of post-mortem examination without search for the tubercle bacilli.

The specific alterations in the lungs in cases of congenital syphilis, chiefly of still-born infants, had long been recognized and their characters were understood. As regards acquired syphilis, there were two forms of pulmonary disease which he had met with and which he thought were syphilitic. One was a form of chronic interstitial pneumonia, beginning usually at the root of the lung and extending along the bronchi and blood-vessels; and the other was the formation of genuine gummata. As to the latter, it had been shown that they might develop as circumscribed syphilitic pneumonias. Although the lesions mentioned were, of course, accompanied with destruction of the pulmonary parenchyma, he knew nothing of the occurrence, from genuine syphilitic lesions, of such destruction of tissue and formation of cavities as we are accustomed to call phthisis. Cavities were indeed found in pulmonary syphilis, but they were always small. In this sense there did not seem to him to have been as yet brought forward sufficient evidence to prove the existence of such a disease as syphilitic phthisis.

Dr. Leonard Weber said that he found himself in accord with Drs. Satterthwaite and Taylor on this subject. In many cases we had undoubtedly a mixed affection, and it stood to reason that a chronic disease like syphilis, in the course of its long history, would often become associated with other diseases. In many patients who had died of phthisis he had found at the autopsy evidences of syphilis in the other organs. After the publication of Fournier's views, however, the tendency had no doubt been to attribute entirely too many cases of pulmonary disease to syphilis. He desired on this occasion especially to call attention to two very interesting cases of syphilitic disease of the bronchi which it had been his privilege to have under observation. One of the patients died, but the other had recovered. The first was a gentleman thirty-three years of age, who suffered greatly from dyspnœa, and had a syphilitic history. A careful examination of the fauces, larynx, and trachea (as far as possible) revealed considerable disease of the bronchial mucous membrane, with thickening, but not ulceration. The treatment, which was partly a mixed one and partly one of plain iodide of potassium, had a remarkable effect in overcoming the attacks of dyspnœa. The patient afterward died of some intercurrent affection, but whether this was of syphilitic origin or not, he had not been able to ascertain. In this case there was, no doubt, a fibroid contraction of the trachea and bronchial tubes as a result of syphilis.

The second was that of a woman twenty-two years of age, a prostitute, who had become infected with syphilis at least six or seven years before, and the characteristic syphilitic perforation of the soft palate. The symptoms,

though not so severe, were very similar to those observed in the other case, and, as in that instance, yielded very satisfactorily to antisyphilitic treatment. The patient had now been lost sight of for some time, though he had no doubt that she was still alive.

Dr. W. H. Porter said that he had tried very hard to secure some positive evidence of the engrafting of tuberculosis on phthisis, but he had never yet succeeded in accomplishing it. He could not see any reason, however, why this should not take place. Post mortem, the diagnosis of syphilis in any case was to be based chiefly on certain changes in the blood-vessels and the absence of tubercle bacilli.

Dr. Taylor said that there was one point which he had neglected to refer to directly, although it could be incidentally inferred from some of the cases which he had narrated. In pulmonary syphilis the correctness of the diagnosis could often be established by the results of treatment. We not infrequently heard of patients being cured of asthma by iodide of potassium, and when this was the case he had no doubt whatever that the asthmatic trouble was of syphilitic origin.

In closing the discussion, Dr. Satterthwaite said that he had expected that an earnest advocate of the other side of the question would be present on this occasion to dispute the conclusions which he had given in his paper, but the gentleman had not appeared. It seemed to him that sufficient evidence had been produced to show that there unquestionably was such an affection as pulmonary syphilis; and this evidence was cumulative. In regard to the pathological changes, we not infrequently found miliary gummy deposits in the lung associated with the characteristic syphilitic cirrhosis of the liver. Such cirrhosis of the liver was peculiar, and very different from alcoholic cirrhosis. Then we had periostitis, and, finally, the clinical history. One peculiar feature was the albuminuria, which was much more common than in tuberculosis. In addition, we had all these signs without any history of tuberculosis.

He then spoke of the peculiar hyaline degeneration of the vessels met with in pulmonary syphilis, and referred again to the case of Dr. Zeh, mentioned in the paper, in which an autopsy was made, where the lesions closely resembled those of tuberculosis, but which were undoubtedly purely syphilitic. Specimens of the lung-tissue were sent to every laboratory in the city, and the reply was made in every instance that absolutely no tubercle bacilli could be found; although some of the microscopists expressed their conviction that the case was nevertheless one of tubercular phthisis.

In reference to Professor Welch's views, he agreed with him that in pure syphilis of the lung the cavities are always small. He regretted that he had had only six cases of his own confirmed by autopsy, but in these the evidence was entirely conclusive. In regard to Dr. Porter's statement that tuberculosis was not apt to be engrafted on syphilis, he said that he had seen cases where syphilis was undoubtedly engrafted on tuberculosis. His experience went to show that in about fifty per cent. of all cases we found tuberculosis together with syphilis. On the whole, however, it must be admitted, as shown by statistics, that syphilis of the lung was comparatively rare.

He was quite willing to admit that there were two views of this question, and that there were good authorities on both sides of it. In his paper he had endeavored to do justice to both. While pulmonary syphilis was comparatively rare, he was convinced that some of the cases entirely escaped notice, being mistaken for bronchitis, broncho-pneumonia, or ordinary tuberculosis. One of the peculiarities of such disease was that while the physical signs were often well marked, the constitutional symptoms were exceedingly slight; there being but little increase of temperature, and the patient's appetite and general health remaining fairly good as well. This was an important point in the diagnosis; as was also the fact of relief secured by the administration of antisyphilitic remedies.

Dr. H. N. Heinemann then read a paper on "Prognosis in Various Forms of Organic Disease of the Heart."

THE BRITISH MEDICAL ASSOCIATION.

Fifty ninth Annual Meeting, held at Bournemouth, July 28, 29, 30, and 31, 1891.

(From our Special Correspondent.)

(Continued from page 221.)

SECTION OF OBSTETRIC MEDICINE AND GYNECOLOGY.

First Day, Wednesday, July 29th.

The President, Dr. Smyly, gave an address in which he urged the importance of not dividing the Section, as some of his predecessors in the chair had proposed, and by means of illustrative cases showed the extreme difficulty, or, in his opinion, impossibility of always distinguishing between the work of the obstetrician and that of the gynecologist. He pointed out the advantages of lying-in-hospitals for teaching purposes, and the great importance of having a gynecological department attached.

Puerperal Fever.—Dr. Smyly then toook up this subject, expressing his strong belief in Semelweiss's theories as to the causation of puerperal fever and gave an account of a septic outbreak which occurred in the Rotunda Hospital. When he was appointed to the Rotunda, in September, 1889, there had been no case of septicæmia in two thousand deliveries. A patient for whom artificial labor had been induced then became septic and soon afterward other cases exhibited septic symptoms. The practice up to this time had been to limit vaginal examination of each patient to three students. Previous to examination the genitals were washed with soap and water, then irrigated first with plain water and afterward with corrosive sublimate solution (1 in 500), the hands of the examiner were also carefully cleaned and washed in the sublimate solution. Vaginal douches after labor were employed only in special cases, and not as a routine proceeding, and plain water alone was used.

After the occurrence of these septic cases all vaginal examination was discontinued and it was found possible to ascertain the presentation satisfactorily by abdominal palpation alone; the condition of the os, of course, could not be ascertained. The septic outbreak now ceased, but on the resumption of vaginal examination again recurred and again ceased when it was discontinued, but this time it recurred while vaginal examinations were not being practised, without any ascertainable cause. The patients up to this time had been accustomed to bathe themselves, but this practice was now stopped and the nurse was directed to do the cleansing, using corrosive sublimate, each patient being kept strictly to the same basin. The septic outbreak then finally subsided and there have since been one thousand deliveries without any sign of septicæmia.

Puerperal Eclampsia.—Dr. Galabin opened the discussion on this subject, drawing attention first to the principal points to be discussed, which in his opinion were: 1, The causation of the albuminuria; 2, the relation of the albuminuria to the convulsions; 3, cases where the albuminuria follows the convulsions; 4, cases where albuminuria is absent.

Albuminuria was often present without producing convulsions, as had been proved by French observers, and as was shown at Guy's Hospital Maternity, where two per cent. of the women had albuminuria, but not convulsions. Women with chronic Bright's disease who become pregnant do not usually suffer from eclampsia. Dr. Galabin considered that the old explanation that the convulsions were due to uræmia was the most reasonable, and that the convulsions were more common in puer-

peral than in non-puerperal nephritis, because of the increased nervous excitability, as was shown by the fact that the fits often occurred with each pain. The convulsions may, in some cases, be due to pre albuminuric nephritis, a condition which has been distinctly recognized in some forms of Bright's disease.

It has been supposed by some observers that the eclampsia and the albuminuria are both due to a common cause, possibly of a microbic nature. A bacillus is reported to have been isolated which produces convulsions when inoculated in pregnant rabbits, but which has no effect on those that are not pregnant.

As to treatment, the speaker said that heroic measures were usually reserved for more severe cases, so that statistics with regard to them were fallacious. The mortality of untreated cases has been stated by Auvard to be twenty-five per cent. Blood letting to the extent of forty ounces or more will stop the convulsions when other means fail, but this treatment renders the patient more liable to subsequent complications, and the evils of its indiscriminate use are shown by the fact that the mortality at Guy's when blood letting was in vogue was thirty per cent., and since then twenty five per cent.

There are two distinct principles of applying venesection: 1, Abstracting a moderate amount to relieve congestion; 2, abstracting a large amount to stop convulsions

As minor measures, Dr. Galabin approved of diaphoretics (hot baths for an hour at a time, followed by hot wet packing), but did not find pilocarpin reliable.

Dr. Byers considered the view that had been held by some, that the albuminuria was due to the fits, was disproved by the fact that albuminuria seldom complicated epilepsy. He narrated a case of a woman who had been pregnant four times, having blood and albumin in the urine each time, but had had no convulsions. He thought that no one explanation would do for all cases, but that there may be several poisons, each producing convulsions. The condition of the fœtus has some effect on the causation, eclampsia being more common in cases of twins.

The speaker said that he believed in milk diet and baths as prophylactics, and when the fits came on he administered chloroform. He had seen serious collapse follow the administration of pilocarpin.

Dr. Auvard thought eclampsia was caused by general deficient elimination by other organs as well as the kidneys. He would treat cases by jalap, digitalis, milk diet, free imbibition of water to flush the kidneys, and diaphoretics. To stop fits he administered chloroform and chloral, employed venesection in plethoric patients, and always emptied the uterus as soon as possible.

Dr. Lawrence thought that no perfectly healthy woman ever had eclampsia. He always insisted on examining the urine of patients whom he was about to attend in their confinements. The treatment he used was the following: Preventive—milk diet, purgatives, and diuretics; when convulsions occur—venesection in certain cases, and delivery. This stops the convulsions, but does not always save the patient. He put the patient at once under chloroform, and then delivered as soon as possible. He said that he had found veratrum viride a good substitute for bleeding in some cases.

Dr. Edis urged the importance, when fits came on, of at once putting the patient under chloroform and injecting chloral per rectum. He advocated also a good dose of morphia, which was not dangerous.

Dr. Swayne gave a record of 36 cases, in 24 of which venesection had been practised and had proved beneficial in 18, being speedily followed by a diminution in the amount of albumin. He thought chloroform and chloral better than opium, and regarded venesection and anæsthetics as the two most important remedies, and after them would place the hastening of delivery. Venesection had gone into disuse partly because of the prejudice against it in the public mind.

Dr. Bell considered general hyperæmia a cause. He did not agree with the statement of a previous speaker that perfectly healthy women were never attacked.

Dr. Godson maintained that when a woman advanced in pregnancy had swelling of hands and feet, if the child was viable, labor should be induced. He narrated a case in which an apparently healthy girl had swelling come on at the seventh month with considerable albumin in the urine. He did not induce labor and convulsions came on at labor, the patient dying. In another similar case he induced labor at the sixth month and mother and child both lived.

The discussion was continued by Drs. Wallace, Macdonald, Heywood Smith, Hanley, and Murdoch Cameron.

Porro's Operation.—Dr Clement Godson reported two cases of Porro's operation. The first case was a primipara, who at the time of operation was suffering from peritonitis, the result of prolonged labor. She was admitted to St. Bartholomew's Hospital, forty-eight hours after the commencement of labor and thirty six hours after rupture of the membranes. The conjugate diameter was two inches. The uterus was exposed and a small incision made through its wall and the opening enlarged by transverse tearing. The pedicle was fixed by one long pin and serrenœud. The fœtus weighed seven pounds. The wound was dressed under spray. The patient died on the second day. The pelvis was removed and its conjugate diameter when dried was two and one-quarter inches. In the second case the conjugate diameter was two inches. The patient was removed to hospital and operated on about twenty-one hours after labor had begun. The child weighed seven and one-quarter pounds. The mother and child left the hospital in three weeks.

In such cases one had to select between Porro's operation and the Sanger Cæsarean. The advantage of Porro was that sterility was ensured, but the same result could be obtained in Cæsarean section by tying the tubes. The Porro was more simple for the general practitioner to do. The difficulty in passing the elastic tube over the fundus might be overcome by threading a wire through it first. He thought every practitioner should be able to do Porro's operation.

Dr. James Murphy then reported two cases of amputation of the uterus during labor, one of which was a woman with cancer of the uterus, who had been in labor three days, the cervix being obstructed by a mass of cancer. The fœtus appearing to be dead the uterus was removed entire. The patient died the next day. The second case was successful.

A discussion followed on the report of these four cases in which Dr. Leith Napier said he had just done a successful Sanger Cæsarean operation. The patient had an attack of influenza after the operation, but recovered. He had previously performed embryulcia on the same patient, and did this operation on the two hundred and eightieth day from the commencement of pregnancy, not waiting for labor to come on.

Dr. Heywood Smith believed that Porro's operation was the better one, and thought that at some future time we might find it possible to treat the stump of a Porro intraperitoneally.

Dr. Murdoch Cameron said that he would not operate on a case before labor had begun, as the dilatation of the os ensured natural drainage. He prepared his ligatures with rectified spirit and carbolic acid. He thought a long incision in the uterine wall was bad. If he found that the incision cut down on the placenta, he put in his fingers and tore the uterine wall and placenta together. He commenced to put in the sutures at the middle of the wound, and endeavored to get contraction of the uterus by pressure before closing the sutures. Gave hot water only, one drachm every fifteen minutes for the first twenty four hours, then small quantities of milk and water.

Dr. M. Handfield Jones narrated cases where obstruction to labor was caused by a fibroid and pointed

out that in such cases Porro was the only operation suitable.

The President said he preferred Cæsarean section, but there were certain cases in which Porro was necessary, namely in rupture, septic condition of the uterus, and fibroid tumors. He thought it was not right to make the patient sterile unless her consent had been obtained.

Dr. Godson, in reply, thought there was no disadvantage in operating before the onset of labor, at all events when a Porro was done.

Tubal Pregnancy.—Mr. Alban Doran reported a case of tubal abortion with double hæmatosalpinx. The patient was twenty-seven years of age and had had attacks of pain for twelve months—a severe attack with collapse just before operation. A two-inch incision was made and the peritoneal cavity was found to be full of dark clot. The left tube was dilated and lacerated; the right tube uniformly distended, and it bled freely from fimbriated extremity. The patient recovered. Microscopical examination showed evidence of tubal gestation which was aborting into the peritoneal cavity. He thought the presence of blood in the other tube was accounted for by reflux from the uterine cavity.

Dr. Lawrence also related a case of tubal pregnancy in which the patient had gone fourteen days over herperiod.

Dr. Cullingworth said he would place rupture of a varicose vein among the causes of hæmatosalpinx. He thought that the thinned-out condition of the wall of the tube was characteristic of tubal gestation, when examined after removal. He doubted whether blood ever regurgitated from the uterus into a tube.

Second Day, Thursday, July 30th.

Uterine Polypi.—Dr. Murphy opened a discussion on this subject. He defined a polypus as any tumor forming a prominence on the inner uterine wall, but excluded placental and malignant and discussed only mucous and fibroid polypi. The mucous polypi were rarely solitary. As bearing upon the etiology he drew attention to the fact that they never occurred in animals. The hemorrhage, symptomatic of uterine polypi usually began as an increase in the amount and duration of the menstrual flow; later it became irregular, coming on especially after exertion. The leucorrhœa was due to chronic endometritis. He did not believe that it was possible to diagnose an intra-uterine polypus by the use of the sound but considered it necessary to dilate the cervix and explore with the finger. When possible, removal of the tumors was desirable. The old method of strangulation by ligature had been abandoned. The écraseur was often useful but there was danger of including a portion of uterine wall in some cases. If the polypus were a large one and situated in the uterine wall he would prefer to treat it by Tait's method of removing the appendages rather than try enucleation.

Dr. Robert Bell believed that fibroid polypi originated as organized blood-clot and were adventitious growths. The mucous polypi were always found in the cervix. In cases of hemorrhage he believes in curetting the interior of the uterus.

Dr. Murdoch Cameron thought there was sometimes great difficulty of diagnosis from inversion in women with fat abdominal walls. He believed in enucleation in certain cases and also thought electricity did good.

Dr. Edis laid it down as an axiom that if there was persistent uterine hemorrhage with no ascertainable cause the cervix should be dilated and the uterus explored. He narrated a case where a large tumor in the vagina was diagnosed as cancer and the patient was treated for some time in the Cancer Hospital. She afterward came under his care and the tumor was found to be a sloughing fibroid and was removed. He preferred to dilate with laminaria tents followed by Barnes's bags. In several cases he had removed small fibroid polypi with the result of curing sterility which had previously existed.

Dr. Heywood Smith did not believe that mucous polypi were limited to the cervix for he had seen them at the fundus uteri. In some cases one had to use the écraseur without first ascertaining the position of the cervix when the tumor was blocking up the vagina.

Dr. Leith Napier thought the most difficult cases were those with a small sessile intra-uterine polypus with great bleeding. He related a case where the ovaries had been removed but hemorrhage did not cease, the os was then dilated and a polypus found.

Dr. Lawrence would limit discussion to polypi only. He believed in the écraseur. He would not enucleate large tumors growing in the substance of the cervix but would use Apostoli's treatment with puncture of the tumor.

Dr. Godson thought that severe dysmenorrhœa, worse on taking ergot, was sometimes a most prominent symptom.

Mr. Alban Doran urged the importance of looking for another fibroid after removing the first one. There may sometimes be an interstitial fibroid as well as a polypus. He questioned whether fibroid tumors ever arose from blood-clot.

Dr. Purslow urged the importance of removing the whole of a sloughing fibroid at one operation and not leaving a portion to be removed subsequently, as had been done by one speaker.

Dr. Travers reported a case of rapidly recurring uterine polypus. A pedunculated fibroid filling the vagina and growing to the uterus was removed by the écraseur. The patient was admitted six months later with a sloughing fibroid attached to the same spot. This was removed and three months later a large sloughing mass the size of the fœtal head was removed by the écraseur and scoop. Six months later a small polypus was removed. Three months later flooding and discharge began again, and a soft mass growing from the same spot was removed by fragments. Sections of the tumors showed fibro-sarcomatous tissue.

Dr. Inglis Parsons asked whether the tumor was sarcomatous from the beginning or had degenerated from a simple fibroid.

Mr. Alban Doran said the tumor was like what had been called a "malignant racemose tumor." In his opinion true malignant degeneration did take place in fibroids. The question of intra-uterine tumors was further discussed by Drs. Godson, Auvard, and Smyly.

The Medical Treatment of Cervical Metritis.—Dr. Auvard then read a paper on the treatment of this disease, which for convenience he divided into three stages. The third, or most severe stage, he treated by cauterization, scarification, and antiseptics. These methods of treatment were applied in the order mentioned. In slight cases, when the mucous membrane only was affected, cauterization was sufficient. For this purpose he condemned both nitrate of silver and the actual cautery, and preferred to inject into the diseased tissues by means of a hypodermic needle a mixture of equal parts of creasote, alcohol, and glycerine. In more severe cases this cauterization was followed by scarification, the latter serving to deplete, and also to evacuate the distended glands. The scarification was effected by a special three-bladed instrument. After scarification the surface was dusted over with powdered salol by means of an insufflator and covered by cotton wool.

In the discussion which followed Mr. Alban Doran urged the importance of limiting this treatment strictly to proper cases.

Dr. Heywood Smith thought Dr. Auvard was wrong in using the cautery first. He had found tampons of glycerine valuable after scarification. He thought it hazardous to carry the instrument into the uterus.

Drs. Travers and Inglis Parsons had used the Apostoli treatment in severe cases.

Dr. Bell thought the endometrium of the fundus was affected and he would treat that.

Dr. Cullingworth thought we knew very little of endometritis, and deprecated vigorous treatment.

Dr. Wallace thought it was usually associated with hypertrophy and treated it by taking a slice out of one lip of the cervix, or incising in several direction with a probe-pointed bistoury, so as to evacuate the glands.

Dr. Cordes showed an aseptic female catheter and an aseptic uterine irrigation tube. The principle of both these was the same, there being a metal or vulcanite rod grooved deeply on each surface. Over this a piece of rubber tubing could be slipped so that the grooves formed channels, the advantage being that the grooves could easily be cleaned and the rubber tube, if advisable, burnt and a fresh one used next time.

Treatment of Pelvic Suppuration.—Dr. Aust Lawrence then read a paper on "Early Incision and Drainage in Cases of Pelvic Abscess." In many cases of pelvic abscess it was impossible to diagnose the exact seat of suppuration, and he deprecated too much vaginal examination as likely to rupture a collection of pus into the peritoneal cavity. In some cases these abscesses ran a favorable course, opening naturally; in other cases they went on a long time or burst into the peritoneum. He held that whenever an abscess was present an external opening should be made as soon as possible, not waiting for fluctuation. He would pass the aspirator needle into a suspicious part of the swelling, and if pus proved to be present he cut down along the needle. If no pus came he left a silver wire in the track of the needle, and the pus when it formed would find its way along the wire and then the sinus could be easily dilated.

Dr. Purslow then reported a case of pelvic abscess (suppurating pelvic peritonitis) treated by combined abdominal and vaginal incision and through drainage. The abscess formed after a premature confinement, and when the patient was admitted to hospital there was a collection of pus reaching up to one inch above the umbilicus, and she had rigors and pyrexia. An incision was made along the outer edge of the left rectus muscle. The pus was found to be in the peritoneal cavity, being limited by slightly adherent coils of intestines. A counter-opening was made in the posterior vaginal wall and a drainage-tube passed right through. This was kept in three weeks and then removed. The patient made a complete recovery.

Third Day, Friday, July 31st.

Treatment of Sterility in Woman.—Dr. Edis reported a number of cases illustrating the cure of sterility.

Case 1. a woman, married thirteen years, had never been pregnant. She had had menorrhagia for two years. On examination villous endometritis was found. The cavity of the uterus was curetted and after some months the patient became pregnant.

Case 2. Woman, married eight years, never pregnant, menstruation was irregular. She was ordered iron, hot douches, and glycerine tampons. The cervix was dilated with graduated bougies, then with laminaria tents. Iodized phenol was applied to the endometrium. After three months, no conception having occurred, an intra-uterine stem was inserted and worn two months, and patient soon afterward became pregnant.

Case 3. Woman, married four years, but never pregnant, menstruation was regular, but accompanied by pain in the iliac regions; dyspareunia and vaginismus were complained of. On examination the hymen was found to be intact, with a small central perforation; it was incised. The uterus was found to be retroverted, and was accordingly replaced and an elastic ring pessary inserted. Pregnancy, however, did not occur, so the cervix was incised, and an elastic ring worn for twelve months. Her health improved and pregnancy occurred.

Only seven per cent. of married women bear children for the first time after three years of married life, therefore the pregnancy in these cases, the speaker thought, might fairly be ascribed to treatment.

Dr. Aust Lawrence drew attention to the fact that sterility may be due to other conditions than local. Pregnancy would not occur in women who lived too highly, or were too fat, or indulged in alcohol. One should make sure also that coitus had actually occurred. He thought the principal local cause was narrowness of the os, and consequent diseased condition of the endometrium. He formerly treated these cases by dilating, but now applies the negative current to the interior of the uterus. He had found that this caused the canal of the cervix to dilate and acted beneficially on the diseased mucous membrane. He drew attention to the fact that in some cases where there is apparent sterility the real condition is frequently recurring early abortion, the patient going a few days over her period and then having a profuse menstruation. These cases were due to a diseased condition of the endometrium.

Dr. Leith Napier would emphasize Dr. Lawrence's remarks about early abortion. He had found a long course of small doses of mercury and iron to do most good. He thought retroversion a more frequent cause of sterility than anteflexion.

Dr. James Murphy thought too much importance had been attached to retroversion as a cause. He had seen several cases where pregnancy had occurred in a severely retroverted uterus.

Dr. Bell thought the cause was almost always endometritis. This might be due to a pinhole os blocking up the secretions, or a flexion might pen up the secretions in the same way.

Dr. Draper recommended chloride of zinc sticks to be passed up and left in the uterus for several days.

Dr. Cordes thought the danger of this treatment was in stenosis of the os occurring from subsequent cicatrization. A sound should be passed into the uterus a few times after this mode of treatment had been employed.

Surgeon-Major Pringle said that in Eastern countries the man was most frequently at fault.

Dr. Edis, in reply, said that he did not think anteflexion was a cause of sterility. He insisted on the importance of attending to the general condition of the patient, and thought that electricity was an efficient agent in some cases.

Electricity in the Treatment of Epithelioma of the Perineum.—Dr. Inglis Parsons recited the case of a woman, thirty-two years of age, who had suffered from an irritable eruption of the perineum for two years. This was at first diagnosed as lupus, but afterward as epithelioma, and was removed by the knife. Eighteen months later the growth recurred. There was then a small mass of epithelioma on the posterior part of the perineum, extending to the anus. As removal would have destroyed the sphincter it was treated by the application of an alternating current of a strength of 400 or 600 milliampères, the patient being placed under ether. The growth separated in a few weeks, the wound healed kindly, and there had been no recurrence. As to the details, he said he used two needles, one being plunged into the growth and the other four inches away. There was danger in applying a current like this near the heart or over the pneumogastric or phrenic nerves, but none in this situation.

The Diagnosis of Spurious and Doubtful Pregnancy.—Dr. Leith Napier then read a paper on this subject. Spurious pregnancy is most common about the period of the climacteric and in young women who greatly desired or feared pregnancy. He then discussed the principal sources of error in forming a diagnosis. The one certain sign of pregnancy, the speaker held, was the fœtal heart-sounds, but these would not be heard when there was extensive hydramnios or the fœtus was dead. Errors in diagnosis might also arise from confusion of one kind of pregnancy with another; for example, the pregnant uterus might be so displaced laterally as to simulate an ectopic gestation.

Dr. Aust Lawrence related a case which came under his notice where the patient was apparently in strong labor, but examination showed that she was not even pregnant.

Dr. Swayne dwelt on the importance of making sure that the fœtal heart-sounds had a different frequency from those of the mother, as mistakes might arise where the maternal pulse was rapid.

Treatment of Chronic Disease of the Uterine Adhesa.—Dr. Robert Bell read a paper on this subject. It was important, he said, to make an examination when there was pain in the ovarian region and at the menstrual period. He thought disease of the ovaries and tubes was always secondary to disease of the uterus, and that cervical endometritis was the most common cause of oöphoritis. The first duty in these cases was to treat the uterus. Inflammation, he believed, extended to the ovaries by means of the lymphatic system. He would always give a fair trial to medicinal treatment before removing the diseased appendages by abdominal section.

Obstetric Operations in India.—Dr. Pringle then read a paper on obstetrics among the natives in India. In the presidency of Bengal where he was situated, no provision was made for skilled attendance on the lying-in woman, and the seclusion in which she was kept was so great that she would rather die than have a male doctor. Thirty to forty per cent. of the lying-in women succumbed to puerperal fever or tetanus during the first fortnight. The birth-rate was sixty per mill and the death-rate forty. The lying-in chamber was a small, dark, damp room in a remote corner of the compound. The midwives were excessively ignorant. The speaker gave details of the cruel outrages which had been perpetrated on young children by the system of child-marriage. He very highly approved of Zenana lady doctors, as it was impossible for males ever to see these poor women.

Dr. Harvey confirmed Dr. Pringle's description of the tremendous evils of child-marriage; he had known one or two instances of death as the result of the consummation of marriage at such an early age.

Dr. Godson showed some improved uterine dilators on the principle of Hegar's, from which they differed in being more pointed and in being hollow, so that they could be packed inside one another, the whole series only weighing twelve ounces.

Therapeutic Hints.

Removal of Superfluous Hair.—Dr. E. O. Leberman, of Akron, O., writes: "In the Medical Record of May 30th, 'Doctor' asks for a 'reliable preparation for removing superfluous hair without the use of electricity.' Permit me to offer the following formulæ, which, in my hands, have proven quite successful. I claim no originality, but offer them as the best of quite a large number which have undergone trial in my hands. The following is the formula recommended by McCall Anderson:

℞. Barii sulphidi ..... ʒ jss.
Zinci oxidi ..... ʒ vj.
Mix with sufficient water to form a paste. Sig.: Apply for three minutes and then wash off.

For the removal of stiff, coarse hair, the formula of Neumann is serviceable:

℞. Calc. hydrat. ..... ʒ jss.
Orpiment ..... ʒ iij.
Amyli ..... ʒ j.
Aq. calcis ..... q.s.
Ft. pasta.

The pastes should be spread over the parts from which the hair is to be removed as thick as the blade of a knife. The softened hairs should be scraped from the skin with a dull knife or ivory spatula, the parts washed with warm water and afterward thoroughly dried. A bland ointment should then be applied to the reddened surface. The length of time these pastes should remain upon the skin is best determined by the severity of their action. They all cause slight itching, which sensation is followed by an intense burning; when the latter begins the paste had best be removed. The effect of chemical depilatories can scarcely be more than temporary, as their action can extend no deeper than the epidermis; the hair-bulbs remaining, a new growth will soon appear. Great care should be exercised in their application, and their effects should be carefully watched, for sometimes deep and painful ulcerations occur by their incautious use. However, they serve a purpose, and if properly applied will often leave the skin free for several months from the hirsute appendages which disfigured it.

To Check the Secretion of Milk, the application of a solution of camphor, one part, in oil of turpentine, six parts, has been recommended. Care must be taken to prevent injury to the skin, for such a mixture would irritate strongly if kept long in contact with the integument under an impermeable dressing.

Carbolic Acid as a Local Anæsthetic.—Dr. C. T. Meacher suggests a five per cent. solution of carbolic acid in water, as a safe and reliable local anæsthetic in dentistry. Four or five drops should be injected under the gum on each side of the tooth to be extracted. He says in most cases this is effective, and where inflammation exists around the root the action is most satisfactory. Dr. Meacher thinks that with moderate care there need be no fear of constitutional symptoms arising, considering the small quantity used. A French dentist, who uses carbolic acid for this purpose, believes that it is equally as efficacious as, and less dangerous than, cocaine.

Aconite as an Antidote to Insect Venom.—A correspondent from Durango says, that formerly about one-half of the children in the city died from the sting of the scorpion, but now nearly all the lives are saved, if taken in time, by the use of a strong tincture of aconite, of which five or six drops are put in a tumbler half full of water, and a teaspoonful given at frequent intervals.—*Medical Times.*

Smoothing out Wrinkles.—The *Medical Press* is responsible for the statement that a curious application has been made of the absorbable properties of lanolin in the treatment of wrinkles. When well rubbed in lanolin passes directly into the skin and acts as a nutriment to the subjacent tissues, with the effect of smoothing out the folds produced by the attenuating of these structures incidental to age. Several elderly ladies who were induced to give this method of treatment a trial, are said to have been delighted with the result.

Plugging the Posterior Nares.—Dr. A. A. Philip describes the following method of plugging the nares for epistaxis in the *British Medical Journal* of July 18, 1891: A piece of old, soft, thin cotton, oiled silk, or silk, about six inches square—a piece of an old handkerchief will answer—is taken, and by means of a probe, metal thermometer case, or penholder, is pushed "umbrella" fashion into the nostril, the direction of pressure, when the patient is sitting erect, being backward and slightly downward. It is pushed on until it is felt that the point of the "umbrella" is well into the cavity of the naso-pharynx. The thermometer case is now pushed on in an upward direction and then toward the sides, so as to push more of the "umbrella" into the pharynx, and is then withdrawn. The closed end of the sac protrudes well into the pharynx, and its open end protrudes at the anterior nares. The inside of the sac may be brushed with some astringent, such as alum, turpentine, etc. A considerable quantity of cotton-wool is pushed well back to the bottom of the sac in the pharynx. Then, the thermometer case being held well against the packed wool, the mouth of the sac is pulled upon, and thus its bottom is drawn forward, and forms a firm, hard plug wedged into the posterior nares.

The sac may now be packed full of cotton-wool, dry or soaked in some astringent solution. The mouth of the sac is tied just outside the nostril, trimmed with scissors, and the ends of the thread secured outside. In removing the plug, open the mouth of the sac, and, with small dressing-forceps, gently remove the cotton-wool bit by bit. If there is bleeding, simply syringe the sac with weak carbolic lotion or Condy's fluid, and repack with clean cotton-wool. If there is no bleeding when the wool is picked out, gently pull out the sac, or if it be adhering to the mucous membrane of the nostril, apply a little warm water, and it may then be easily removed.

The Effect of Drugs on the Action of the Heart.—Dr. Germain Sée recently presented a communication to the Paris Academy of Medicine regarding the influence of drugs in cases of dilatation of the heart, in which he drew the following conclusions: 1. Sparteine is the drug which diminishes most, and most rapidly, the size of the heart, it strengthens the cardiac muscle most, by increasing its tone and elasticity; on the other hand, with this drug, there is an absence of diuresis. 2. Digitaline diminishes equally the volume of the heart, but acts chiefly on the right cavity, and it only seems to act on the right side if the cavities are previously dilated by some definite pathological condition. 3. Iodide of potassium diminishes the volume of the heart, but in a less degree than sparteine. 4. Antipyrin increases the gross bulk without exercising any influence over the contractile power, or consequently on arterial tension. 5. Bromide of potassium has a similar action to antipyrin, and an opposite effect to iodide of potassium. It dilates the whole of the heart, perhaps chiefly the right side. Caffeine, although an excellent diuretic, has no action on the cardiac muscle. This paper gave rise to an animated discussion, Dr. Dujardin-Beaumetz and others considering that the evidence adduced by Dr. Sée did not at all justify such sweeping conclusions.—*Provincial Medical Journal.*

For Corns and Warts.—A mixture of one part each of lactic acid and salicylic acid in eight parts of collodion, is recommended as an excellent application to warts or corns, effecting their removal in a short time.

Menthol in Hay Fever.—Dr. Lennox Wainwright writes to the *British Medical Journal* that he has found menthol of great service in hay fever. It acts best when placed in an ordinary smelling-bottle mixed with carbonate of ammonia, and used as smelling-salts. Patients say all irritability disappears, and in many cases they get no return of the symptoms.

Preparing the Skin for Antiseptic Operations.—Dr. F. W. Langdon, of Cincinnati (*Lancet-Clinic*), calls attention to the value of benzine as a solvent of oily secretions in the preparation of skin areas for antiseptic operations. An agent that can penetrate and disinfect the pores and follicles of the region to be operated upon, has advantages not possessed by any of the watery solutions in common use.

Borax in the Treatment of Epilepsy.—Dr. Dijoud has tried this remedy in twenty-five cases, and he claims to have entirely cured one, and to have relieved all except six. The duration of the treatment varied from one to seven months, and he was able without inconvenience to carry the dose up to ninety grains a day This was only possible if a beginning were made with small doses, which were gradually increased; and when the dose exceeded sixty grains daily he found it advisable to add some glycerine to the water and syrup in which the drug was usually administered. The patients to whom Dr. Dijoud administered borax had been treated unsuccessfully with the bromides.

Thymol in Chyluria.—Dr. E. Lawrie reports two cases of chyluria, due to the presence of filaria in the blood, cured by thymol given in doses of one grain, gradually increased to five grains, every four hours.

Chlorosis.—Dr. Brinton recommends the following combination of iron and arsenic in the treatment of chlorosis in young women:

℞. Acidi arseniosi ..... gr. 1-60
Ferri sulphatis,
Potassii carbonatis.....āā gr. jss.
M. et fiat pilula. Sig.: Begin with three and increase to six pills daily.

—*College and Clinical Record.*

Treatment of Erysipelas.—Dr. C. W. Allen, of New York, in an article on the treatment of erysipelas, in the July issue of the *American Journal of the Medical Sciences*, recommends the following: Internally, such symptomatic treatment is followed as the nature of the case seems to require. Locally, he advises painting the patch and surrounding margin of healthy skin thickly with ichthyol in collodion, ʒ j.–ʒ ij. to ʒ j. If the scalp is the region affected, a watery solution or ointment of ichthyol can be employed. In every case an attempt should be made to arrest the spread either by the band of adhesive plaster or by scarification, or both, the latter to follow the former, in case the disease spreads beyond the adhesive strips. In erysipelas of the face which has not yet reached the forehead, or at least its upper part, a band should be applied tightly about the forehead and just above the ears, the hair being cut if necessary to secure firm pressure. The chances of arresting the process here should be at least equal to those of checking the spread upon an extremity, for we have a hard bony base over which to make our compression. If the boundary is passed, then the scalp should at once be shaved and another band applied higher up. The hair should be cut in any case in which the scalp is invaded or threatened. Then the same application of ichthyol in collodion can be made, as to the face or other part. If there be much tension, swelling, heat, and discomfort (which is not apt to be the case under collodion), any oily substance can be applied over it.

Peroxide of Hydrogen in Asthma.—Dr. I. W. Chisholm, of New Concord, O., says that for the continuous treatment of asthma, in the intervals of the paroxysms, he has found nothing equal to peroxide of hydrogen by inhalation. He also, in conjunction with this, advises the use of strong coffee at meals, and whenever desired by the patient. For the paroxysms he finds that morphine hypodermically affords the most speedy relief.—*Columbus Medical Journal.*

Thuya in Hydrocele and Hæmorrhoids.—Dr. Howe, of Cincinnati, says that a diluted tincture of thuya occidentalis injected into the tunica vaginalis testis is of great service in hydrocele. If well injected and squeezed into every part of the sac, this will be obliterated, and the effusion will not return. Injections of thuya into hæmorrhoidal tumors promotes their destruction with more certainty and less danger than does carbolic acid.

Donovan's Solution in Gleet.—The solution of the iodide of arsenic and mercury is said to be of material service in the treatment of gleet. It is given for this purpose in the dose of ten minims, three times a day. A correspondent writes that he feels justified, so uniform has been his success in controlling a chronic urethral discharge by Donovan's solution, in calling the remedy almost a specific for gleet.

A New Remedy for Ivy Poisoning.—Dr. James J. Levick, of Philadelphia, writes to the *Medical News*: "In a case of poisoning of the hands from *rhus toxicodendron*—poison oak—recently under my care, which had reached the vesicular stage and was attended with much swelling and burning, the happiest results promptly followed the free dusting of the powder of aristol on the affected parts. The change was almost magical, so sudden and so prompt was the relief afforded. Might not this powder, applied in the early stage of the disease, do much toward preventing the ulceration and pitting of variola?"

Correspondence.

POLITICS AND INSANE ASYLUMS.

To the Editor of the Medical Record.

Sir: Your editorial, in a recent issue of the Medical Record, upon "Politics in our State Insane Asylums," based upon a report of the meeting of the State Commission in Lunacy with the managers and superintendents of the State insane hospitals, must have shocked all who were present at that meeting, as it did the writer.

The only reference to politics at the meeting was made by a Commissioner in Lunacy, who made the reasonable suggestion that county officers of the poor did not exert themselves to the utmost in inducing friends to take relatives from the hospitals who were able to leave, although not recovered, for fear of exciting the enmity of their constituents, and inviting "political disaster." On the other hand, it was admitted that medical superintendents used all means within their reach to induce relatives to take suitable cases from the hospitals. The additional officer it was proposed to add to each hospital was not considered necessary, as he could not effect more than can now be attained by suitable persons already employed upon each hospital staff, and he would be a supernumerary. With this the Commission concurred.

Very respectfully yours,
P. M. Wise,
Sup't of St. Lawrence State Hospital.

[We publish the above note with pleasure, but the fact remains that there are persons kept confined in lunatic asylums because their friends have political influence. The remarks of the Commissioner, as we are informed by Dr. Carlos MacDonald, were called forth by the reading of a letter from a County Superintendent of the Poor stating that there were several patients from his county in the State hospitals, as a county charge, whose friends were able to pay for their support, but who evaded doing so through political influence, and that to complain of this would jeopardize his, the County Superintendent's, official tenure. We are sincerely glad to believe, on the assurance of those best informed in the matter, that the New York State Hospitals for the Insane are free from partisan influences, but it would seem that the County Superintendents of the Poor need looking after.—Ed.]

THE HANK TRUSS AGAIN.

To the Editor of the Medical Record.

Sir: The only criticism of my article on the "Treatment of Hernia in Children by Means of the Hank Truss," which was published in the Record, May 30, 1891, occurred in the issue of July 18th, under the head of "Correspondence." The other unfavorable remarks, which were limited to one written communication, read by the Secretary of the Surgical Section following my paper, could only apply to the principle of the hank truss, as the author was unable to know what I claimed, or the results shown. The fact that cases were presented after having worn a truss from a few days to several weeks, and others whose hernias had been cured for some months, all to the satisfaction of the members of the Section present, was my reason for not making a reply. The question to be asked, Does the hank (or worsted) truss afford sufficient support for the cure of hernia? Clinical facts speak quite in the affirmative; but I am pleased to know that others have had as good, or better, results with it than I claim. The following communication, from Dr. R. W. Lovett, of Boston, is offered for publication with his consent:

Dr. S. E. Milliken.

My Dear Dr. Milliken: I still use the worsted truss on practically every case of hernia in children that comes under my care. I cannot speak from anything more than my personal impression in telling you about my experience with it; but it seems to me to meet the work better than any of the spring trusses, and to be more efficient than they are, even in the case of children eight and ten years old. I have recently had two cases of hernia occurring in boys six and eight years old, where, by the use of the worsted truss, and a good deal of care on the part of the parents, the hernia was, so far as I can judge, entirely cured. Two cases of incipient hernia have been entirely cured. I have about one hundred and fifty cases of hernia in children, which I am investigating as to the end results. I have not got far enough with them to speak of the efficiency of the worsted truss; but when they have been analyzed I think that I shall have some definite data.

In the meantime I can only give you my impressions that the truss is by all means the best one in cases of young children; that it affords a definite and non-irritating support to the inguinal ring; and that it is much more easily managed by the parents than the other forms of truss.

If I have said anything that is of use or interest to you it is quite at your disposal for publication or anything else, and if there is any further information that I can give you I will gladly do so. I use the truss in my clinic practically as a routine treatment.

I am, very truly yours,
R. W. Lovett.

At the Hospital for Ruptured and Crippled, where something over three thousand cases of hernia (adults and children) are treated annually, it is found that a small percentage are not relieved, whatever truss may be used. These are the unintelligent and careless patients on whom no truss will be worn twenty four hours as first applied, and failure in such cases should not condemn to utter uselessness an apparatus that has proven highly successful both in hospital and private practice. In this day of dispensaries, when patients have such a number to choose from, no one expects to be able to follow every case to its termination, and I believe due allowance was made for the shortcomings of such patients in my original article. I do not use the hank truss to the exclusion of all others, but decidedly in the majority of my cases under one year of age. Mothers have even objected to the change from a hank to a celluloid or hard rubber truss, in occasional instances, when I considered the spring truss more safe in children just beginning to walk.

Respectfully,
S. E. Milliken, M.D.

157 Madison Avenue.

Navy News.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 22, 1891.

Du Bose, W. R., Passed Assistant Surgeon. Ordered to duty at Naval Academy, Annapolis.

Harmon, G. E. H., Surgeon. Detached from Naval Academy, Annapolis, and wait orders.

Wells, Howard, Surgeon. Ordered for temporary duty at Naval Station, New London.

Hoehling, A. A., Medical Inspector; Parker, J. B., Surgeon; and Norton, O. D., Passed Assistant Surgeon. Ordered to Naval Academy, Annapolis, September 3d, to examine, physically, candidates for admission to the Naval Academy.

Total Helplessness, according to a pension bill introduced into the United States Senate during the last session of Congress, is caused by the loss of a leg or arm so close to the hip or shoulder that an artificial limb cannot be worn.

PULMONARY CARCINOMA AND SARCOMA.

TWELVE CASES, WITH ILLUSTRATIONS.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

THE chief object of my paper is to add a few contributions to a matter that is comparatively obscure, and where any new data have practical value for the physician and surgeon.

I will venture to state at the outset (to avoid misunderstanding and confusion) that I shall not make any distinction between pulmonary and mediastinal tumors. I do so for the following reasons: Anatomically speaking, we recognize the three mediastinal spaces as valuable in student life for locating certain organs or systems; but from the stand-point of the pathologist or clinician we do better to overlook them. They are unnecessary, because we connect in our minds any given lesions with the parts that occupy the spaces, rather than with the spaces themselves. Besides, I doubt if any disease of importance originates in the proper tissue of the mediastinum, unless it be abscess, and even then an abscess does not rise to significance unless it attacks glands, vessels, nerves, lymphatics, the pleura or pericardium, etc. In fact, although elaborate and systematic articles have been written on diseases of the mediastinum, by continental physicians and others, I do not remember to have known or read of an instance where the description would not have been clearer if the term mediastinal had been altogether omitted.

This view appears to have been quietly sanctioned by standard writers on pathological anatomy,[2] while clinicians generally are relegating the mediastinum to a very subordinate position,[3] if they mention it at all.

Briefly, again, it may be said that mediastinal growths never yield clinical symptoms until they have either invaded the substance of some important system within their boundaries, or of some contiguous tissue, like the pleura or pericardium.

Tumors of the lungs are either, 1, carcinomas; 2, sarcomas; 3, lymphomas (Hodgkin's disease); 4, composite growths; 5, dermoid cysts; possibly, 6, enchondromas; or, 7, fibromas. In the following statements I shall call attention to only the more common of them, viz. carcinomas and sarcomas; my object being, primarily, to indicate the means we have at present for making a differential diagnosis *intra vitam*.

At first sight it may appear strange that we have so little information on this topic, considering that carcinomas are very common, and sarcomas diseases that every physician meets with occasionally in his practice.

In explanation, however, it may be said, first, that lung implication in cancer is comparatively uncommon; then again, it occurs during a late period of life, when the primary disease or its more immediate consequences have so overshadowed the visceral complications that they have either escaped observation, or (if detected) have been held as comparatively unimportant, in the face of inevitable and impending death. Besides, the vast majority of reported cases have to be disregarded, because their pathological history is so unsatisfactory as to be almost worthless; or, where the pathological account happens to be worthy of consideration, the clinical history is apt to be entirely lacking, perhaps because it has been neglected at the bedside, or because (for some other reason) it has been inaccessible.[1]

I presume there are some here to night who are lamenting with me that the scientific physicians of Germany have added so little to practical pathology and clinical medicine during the last few years.

Bent on worshipping the false gods of personal or political pathology, they are only just beginning to find out their errors, which have been the more disastrous for scientific medicine, because the civilized world had begun to feel that Germany was the fountain-head of medical inspiration.

Let us hope that the coming reaction in the public mind against scientific research, which will inevitably take place, will only be temporary. At any rate, let us remember that there is such a thing as false pathology; and again, that sound pathology without its application to clinical medicine or surgery is of curious interest, and not of practical value.

Pathology forms the true groundwork of medicine, in its application to the wants of mankind; but if the foundation stones are laid in mire and quicksands, the superstructures will, sooner or later, totter and fall.

There are, however, in our literature, some conspicuous instances where pulmonary tumors have been studied and recorded from the bedside to the autopsy table, and in an instructive manner. They will be alluded to in this paper; and I am glad to say that American contributors hold a prominent position in the list, even if it be a very short one.

Carcinoma of the lungs, has of course, been frequently described, though for reasons just given the data have not been of much service to me in this paper. I doubt if the clinical histories of its several varieties have ever before been laid down. If so, I have been unable to find any systematic mention of them. There are three forms that I will briefly describe.

The most common is the medullary or encephaloid, vulgarly known as rose cancer (Fig. 1), which I believe to be invariably secondary to disease elsewhere, as in the uterus, breast, pancreas, etc. From my own records of three hundred cases, as tabulated for me some years ago by Dr. J. C. Bailey, I found that it occurred more frequently in the liver and breast than in the lung, being *par excellence* that form which secondarily attacks internal viscera. It may be expected in the lungs in only about ten per cent. of these internal recurrences.

Medullary cancer occurs most frequently in the fourth decade of life, but may appear as early as the third, or as late as the sixth decade. As the primary disease is chiefly located in the uterus or female breast. Hence medullary cancer of the lung is essentially a female disease. It develops rapidly (as a rule) and is apt to become bulky; but it degenerates early, owing to the paucity of its vessels, deficiency in fibrous tissue, and preponderance of epithelial or other cellular elements.

Pain is a marked feature of the disease, but it is chiefly due to pressure. Cough is not always present (as Walshe

[1] Read before the Medical Society of the County of New York, April, 1891.

[2] Compare works of Green, Coats, Cornil and Ranvier.

[3] Compare among writers on clinical medicine Niemeyer and Flint.

[1] Allusion is here made to the chief contributions on this subject as found in Virchow's Archives.

has claimed), nor is there necessarily any expectoration of catarrhal or bloody matter. The affected side may shrink or bulge out. When the deposit has attained the size of a hen's egg it may usually be mapped out; as it occurs in the parenchyma of the lung rather than at the root. Here is a sphere in which auscultatory percussion should earn its laurels. Dulness at first will be followed by flatness, if any considerable portion of the lung is invaded (as a lobe, for example). "Blowing tubular respiration" is a very prominent sign, and Walshe [1] has very properly called attention to it. The duration of medullary cancer is difficult, and in fact, impossible to estimate, but its short continuance is largely to be laid to coincident cancerous infiltration of other parts, and the profound constitutional disturbances which they jointly produce.

At best, this type of cancer exists but a few months in the lungs. But it is this straw that may break the camel's back. My statistics in all cases of medullary cancer (including the lung complication), make five months the average duration of life. But I may as well say here, that in statistics of carcinoma generally, the two forms, scirrhous and medullary, have so frequently the relation of cause and effect to one another, that they cannot be separated statistically. With this view of their relation in mind, I may again call attention to some figures I gave in 1885.[2] At that time I had under observation, or was in communication with, eight patients from whom a breast had been removed for cancer from seven to thirteen years previously. Some of them were fairly well at that time, and some may still be alive. In advanced life the progress of cancer is slow, and often appears to be arrested for considerable periods of life. This rule is especially applicable to people in the seventh to eighth decades of life. The favorable statistics alluded to in breast cancer are seen only in about ten per cent. of all breast cases, and my percentage agrees in this respect with that of the late Dr. Samuel W. Gross, one of the most exact and painstaking of our surgical pathologists. Of the remaining ninety per cent. the average duration of life is about twenty-five months.[3] Walshe has put the duration of lung cancer at from three to twenty-seven months. But for reasons already shown, the average duration of cancer can only be reckoned approximatively.

I may add here, parenthetically, that in all my cases of breast cancer, excision had been practised, and I take this opportunity of stating again, that I believe the good results were largely due to early and thorough operative measures.

In medullary cancer there is sometimes acceleration of the pulse and rise of temperature, but these signs are not constant. Chills and sweats may also occur, but they are probably due to absorption of disintegrating matter. Emaciation always is found in advanced periods of the disease.

The second form of cancer that I have seen in the lungs is the squamous epithelioma—common upon the lip and external genitals. It is seen about the middle periods of life; is secondary; but owing to the small size of the deposits, whether single or multiple, they may for a considerable time escape detection. Death occurs about six months after the inception of the primary disease, to judge by my cases, where the whole course of the primary and secondary growths has afforded opportunities for studying them. The tongue and œsophagus are favorite starting-points. Death, in these instances, is largely due to mechanical interference with deglutition. The symptoms are similar in general character to those of medullary cancer, but differ in degree rather than in kind. They are milder in character and slower in progress; occur chiefly in the male sex, in the fourth to sixth decades of life; and are found, as a rule, at the root of the lung, though they may also be scattered through the parenchyma. Sometimes they develop by extension from without into the lung, as in epithelioma of the œsophagus.

In justice to others I must here state that a third form of lung cancer has been described at length by continental and other writers.[1] Of it I have had no personal experience in the lungs. I refer now to a type of epithe-

lioma that has been called cylindrical epithelioma (Fig. 2), which has been quite frequently confused with papilloma, as the two often originate from the bronchus, and at an early period of their growth are indistinguishable. In its full development it is known as the "cauliflower growth." Developing in tissue contiguous to, if not in actual contact with, the lung, it has sometimes been classed under primary cancers of the lung, leading, of course, to much confusion.

The clinical history given is as follows: Occurring mostly in the third decade of life, it (like the preceding form of epithelioma) appears to be a disease of the male sex. Duration is brief, usually from five weeks to six months. Subjective signs have been dyspnœa and pain, referred to a pleurisy. Cough is common, as also expectoration, which may be pink or bloody. Hæmoptysis moderately frequent. Bulging of the chest as noted in two instances is naturally to be expected, because the growth is apt to be bulky. Pulse and respiration may be

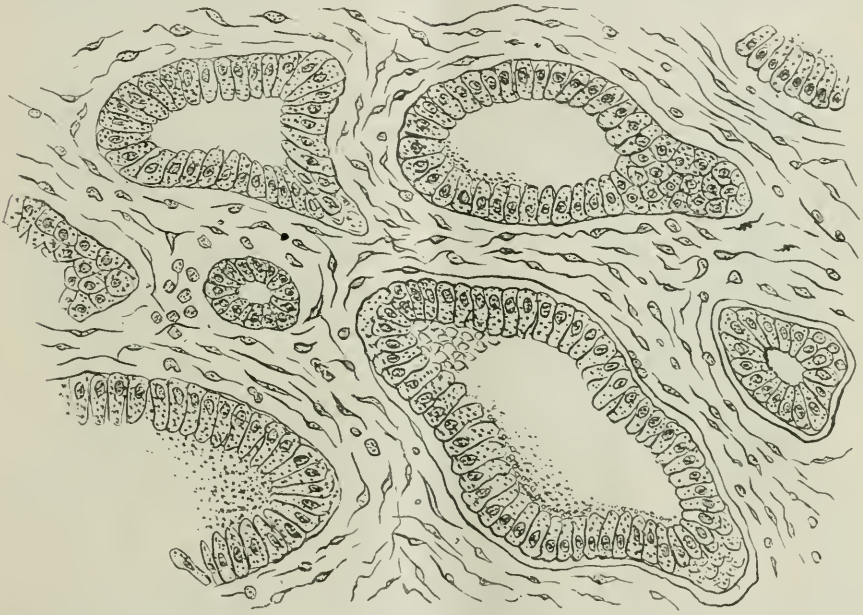

Fig. 2.—Cylindrical Epithelioma. × 200.

accelerated. The former may rise to 120. The temperature may also be elevated.

On percussion dulness or flatness will be elicited, according to the area or location of the deposit. On auscultation, the breath-sounds may be faint or absent, especially if the disease originates within a bronchial tube. At an early period, coarse or moist râles may be expected, and prolonged expectoration due to compensatory emphysema or obstruction in a bronchus. Over the flat area vocal fremitus may be absent. This has been held by Wintrich to be a pathognomonic sign. It is not a reliable sign, however, in all cases of lung tumor, as it may go and come. In this particular variety of cancer (that is especially apt to occlude larger air-tubes) it may prove a valuable diagnostic factor.

At the circumference of the deposit, if large, respiration may be high-pitched. The heart's apex may also be displaced. Owing to the fact that the deposit is apt to be at the root of the lung, dysphagia may be expected. Pleurisy, wet or dry, may occur or may not. Enlargement of the superficial veins has been noted. In some instances there has been cyanosis, or a dusky hue of the countenance. Sometimes there has been œdema of the neck, due probably to glandular implication. The prevertebral and bronchial glands appear to have been affected in all instances. Emaciation is a prominent feature.

The above illustration (Fig. 2) was taken from a specimen of cylindrical epithelioma in my possession, though it did not occur in the lung.

Sarcomas of the lungs come second in order of frequency (Figs. 3 and 4). But few cases, however, have as yet been recorded with satisfactory clinical and pathological details; one such, however, has been given by Fraser (*Edinburgh Medical Journal*, 1880, p. 1). It came under observation in 1879, and the whole record that has been furnished is a model of pathological exactitude and clinical thoroughness, that should be an example for us all to follow. I regret that the limits of this paper prevent me from quoting it at length. The following experience has been taken from seven cases, from which I have gleaned the following generalizations. Sarcomas usually develop in young people, *i.e.*, within the second or third decade of life. They are always secondary formations when found in the pulmonary tissue. They give no symptoms until as large as an English walnut, but often pass undetected when as large as a hen's egg, or even a man's fist. Hence it is impossible from present statistics to determine their average duration. As in cancer, the primary and secondary diseases have to be considered together, if we desire to reach any conclusions, even if they are only approximative. From this point of view the disease may last from eleven months to five years. I allude entirely to fatal cases. But in many instances we have no record of a recurrence, and the surgeon may feel confident that his operation has effected a cure. In this connection I should say that the microscopic diagnosis of sarcoma often presents unusual difficulties, especially in round-celled sarcomas (Fig. 3), where a differential diagnosis between the neoplasm and a simple inflammatory deposit may be impossible, apart from the clinical history. Sometimes sarcomas are pigmented, as in the tumor from which my drawing was made. In them there are hardly any difficulties in the way of a microscopic diagnosis (Fig. 4). In some of my non-fatal cases

many years have elapsed without a recurrence. In a case given by Drs. Girvin and Formad, of Philadelphia,[1] the patient survived ten years.

The life history of sarcomas, however, begun in such magnificent style by the late Dr. Gross, has yet to be completed. At present we know very little about them.

In six of my fatal cases the average duration of life was forty-four months, or about twice that of scirrhous cancer.

As soon as the lung has been invaded, especially in sarcoma of the long bones, the regular symptoms are dyspnœa, and pain that is described as violent or "stitching," as in pleurisy. Occasionally there is cough, and the expectoration is apt to be abundant, sometimes mucous in character, sometimes streaked with blood. At first, lung expansion may not be interfered with, but as the growth extends it will diminish, and may cease altogether. Sometimes the thorax will be expanded by the bulkiness of the tumor, or it may be retracted; and the difference will depend rather, I think, on the texture of the tumor, than on its bulkiness. In general, the greater the cellular element the greater will be the chest-expansion; on the other hand, when the fibrous element is in excess contraction is to be expected. Where both lungs are involved, it may be difficult to determine whether the thorax is contracted or expanded.

The pulse will increase in frequency according to the area of pulmonary tissue involved, other things being equal. It may reach 90 or 100, but rarely exceeds this last figure. Elevation of the temperature is not usual at first, but is customary toward the fatal issue. It may reach 100° or 104° F., or upward. Such a rise of temperature may, I think, be due to the absorption of disintegrating particles of a degenerative character, as the growth will inevitably soften when it increases in bulk.

Absence of fever at the outset, when dulness is first appreciated, is of regular occurrence and constitutes an important negative sign.

The respiration increases in frequency contemporaneously with the pulse, and may reach 24, 32, or 40.

On percussion, dulness will be found as soon as the deposit attains any considerable bulk, and flatness will follow, when a considerable area of the lobe is involved. As pleurisy will certainly occur when the growth reaches the pleural surface, we should be on the lookout for a plastic or watery effusion.

On auscultation, there will be noted, in almost all instances, the mucous râles of bronchitis, or perhaps more properly of bronchorrhœa. This is an early sign, but may merely denote that the secretion is delayed in the larger tubes, by deficient expansion, or by pleuritic exudations.

Bronchial breathing and bronchial voice are to be expected when the larger air-tubes are pervious and the neoplastic growths lie between these tubes and the listening ear. As the result of pressure on the lung or undue efforts at respiration, there may be more or less of compensatory emphysema, such as occurs in phthisis or in any form of lung consolidations. Furthermore, as I have already intimated, the regular auscultatory signs of pleurisy should be expected.

Over the area of dulness vocal fremitus may be absent. How valuable this sign is I do not know.

In Fraser's case there was marked "arching" of the sternum, fulness in the axillary and infra-axillary regions, intercostal pulsation and cutaneous hyperæsthesia. These symptoms were absent in my cases, or, at any rate, were so subordinated to the others mentioned that they were not noted. Toward the fatal termination there will be emaciation and occasionally night-sweats. The disease is, as I have already stated, secondary. I have never seen or read of a case that has convinced me to the contrary. Hence, the most important diagnostic factor is the history of a primary disease. In three, or nearly half of my cases, it was secondary to bone sarcoma, and there was no difficulty in determining *intra vitam*, with a great degree of certainty, the general character of the secondary formation. Sarcomas may develop either from the periosteum, bone marrow, or from the intermuscular planes, as those of the thigh, from the fibrous septa of the brain as in Dyce Duckworth's[1] case probably, or from any interstitial connective substance.

Fig. 3.—Mixed Sarcoma of the Lungs. × 200.

From the foregoing facts, all of which have been derived from genuine cases of disease, it will appear that we are furnished with a large number of data, some of which are sufficient to enable us to make satisfactory diagnosis as to character of the lung deposit.

In another class of cases we have to reason by exclusion in the main.

[1] Girvin: Transactions of Pathological Society of Philadelphia, x., p. 112.

[1] Dyce Duckworth: Transactions of the Pathological Society of London, 1884-5, 13, 120.

Pneumonia, whether lobar or bronchial, has its own peculiar history, as indicated by the characteristic chill, adhesive sputum, rapidly increasing area of dulness or flatness, limited period of fever, abnormal relation between pulse and respiration, possibly by the occurrence of the pneumococcus.

Phthisis has the family history, characteristic sputum, diurnal temperature—variations, early implication of apices, presence of bacilli, and diarrhœa.

Aneurism is excluded by the absence of murmurs, of circulatory disturbances, and by the vascular tumor. In pleurisy with effusion we may have difficulty, but its sudden appearance, with friction-sounds, alteration of level of fluid to correspond with changing position, and finally the aspirating needle, should enable us in most cases to overcome the difficulty.

But these are negative signs. The positive are, first, in most cases, an external primary growth that has been examined so as to determine its microscopic characters. Then, after a variable time, the sudden appearance of a pulmonary deposit, without any acute phenomena except those that are called "pressure symptoms," including dyspnœa, pain, or change in the shape of the chest.

Though there are many sorts of tumor that have been described as belonging to the lung, some are so rare and doubtful that for practical purposes we may exclude them and limit our study to carcinomas, sarcomas, lymphomas (lympho-sarcomas), composite growths, and dermoid cysts.

Now, of these we may usually eliminate dermoid cysts, because according to our present knowledge they occur almost exclusively, if not invariably, in females, and are distinguished by spitting of hair from time to time. In composite tumors there has been always a primary tumor of the testicle or of the parotid region. Exceptions to this rule are doubtful. In excluding Hodgkin's disease (lymphoma), we may have difficulty, as my experience has shown, when the disease originates in deep-seated and inaccessible lymphatic glands; but when it originates in the neck, groin, or axillary region there should be no difficulty, as the peculiar enlargement of the glands and the infiltration of the periglandular tissue is unlike anything else, and the diagnosis can be almost made at the first glance. Furthermore, we invariably find in Hodgkin's disease, as the disease advances, more or less anæmia and dropsies, and general implication of internal viscera, such as the liver and spleen.

In the differential diagnosis between sarcoma and carcinoma, we have in each an antecedent primary focus, which in the majority of my cases appears to have been easily diagnosticated, especially after removal by surgical means. Sarcoma is also pre-eminently a disease of early life as I have said—the second and third decades; carcinoma of the fourth, fifth, and later periods. In sarcoma the recurrences, if they occur, are apt to be local for a time. The lung is only attacked after the disease has existed for some considerable time. In carcinoma the lungs are apt to be involved at a comparatively early date. In sarcoma we find the same class of physical signs as in carcinoma, but they are less pronounced, as a rule. In a certain number of cases the diagnosis presents what are now insurmountable difficulties, as for example where a carcinoma starts from a bronchus, or a sarcoma from the periosteum of the body of a vertebra. But even in such instances the diagnosis has been made as in Dr. Girvin's patient, where Dr. Formad determined its character by a microscopic examination of expectorated matter. Such good fortune as to obtain a portion of the growth by expectoration, is, I fancy, very rare. In all forms of lung tumor auscultatory percussion has a useful sphere. Thus far it does not appear to have been practised successfully to any very great extent.

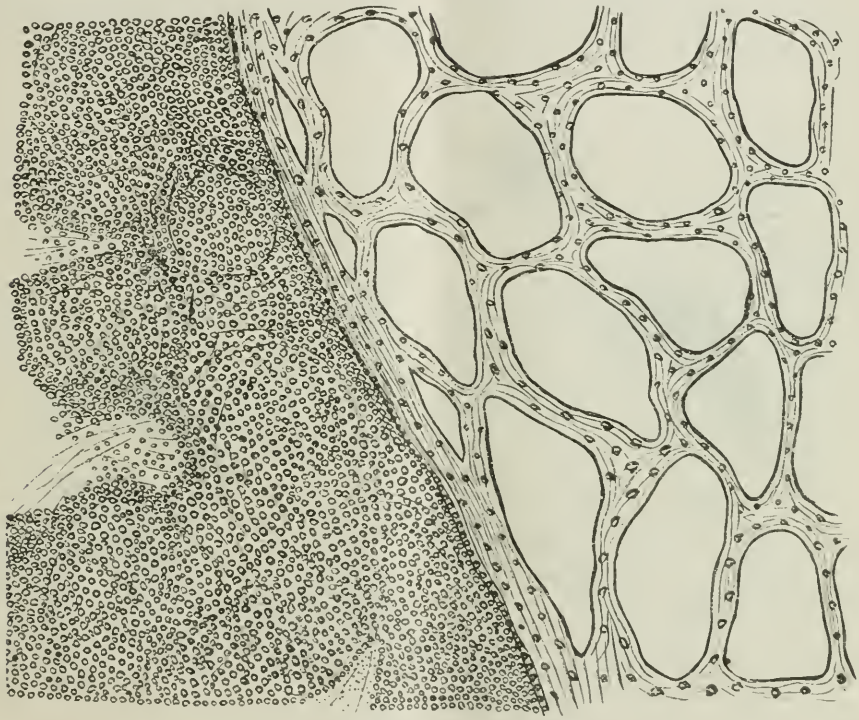

Fig. 4.—Small Round-celled Sarcoma of the Lungs. × 200.

If from the foregoing statements of facts, and of inferences drawn from them, I have made this topic any

clearer, the purpose of the paper will have been accomplished.

Case I. *Medullary Carcinoma of Uterus and Lungs.*—E. W——, aged thirty; domestic; was admitted into hospital on May 20, 1890. In the preceding January, after injuring herself by a strain, from helping to move some furniture, she had a miscarriage between the second and third months. Had flooding eight weeks later, and then again after an interval of three weeks. On examination it was found that a large mass occupied most of the pelvic cavity. The patient dying suddenly, it was found that a hemorrhage had taken place into the abdominal cavity, producing almost instant death from great loss of blood (forty-six fluid ounces). A carcinoma of the fundus uteri had extended so as to involve the right ovary, and it was this mass that had been felt during life and which was the source of the hemorrhage. The lungs contained nodules in size from a pea to an English walnut, and microscopic examination proved that they were carcinomatous in character. No pulmonary symptoms noted during life.

Case II. *Carcinoma of Breast and Lungs.*—M——, aged fifty-six; married; admitted to hospital July 18, 1879. Had experienced the operation for removal of mammary carcinoma on two occasions, the first two years before, the second one year ago. For three months had felt pain in back between the shoulders. Shortly after admission, paralysis of right lower extremity occurred, then paralysis of both lower limbs. At post-mortem examination softening of the cord was found in the dorsal region, and cancerous nodules projecting into the spinal canal. In the brain there were adhesions between the pia and dura, and a gelatiniform deposit with fibrinous thickening along the course of cerebral vessels.

In one lung were found in the lower lobe cancerous nodules the size of a hen's egg. Liver and broad ligament also contained similar nodules. No pulmonary symptoms during life.

Case III. *Carcinoma of Pancreas, Liver, Kidneys, and Lungs.*—M. N——, aged forty-nine; domestic; admitted to hospital June 18, 1881. Family history phthisical. Five years before admission complained of pain in her chest. Pain lasted one year. Three months before admission began to have pain in her side. Has had irregular chills, fever, and sweats. Urine contained a little albumin, some blood, and granular casts.

Physical examination reveals flatness over left thoracic cavity behind, from one inch below angle of scapula to base. Corresponding respiratory murmur feeble. "Blowing" character noted in respiration for two inches about this area of flatness. In front fair resonance with exaggerated respiratory murmur. Left chest measures 15¾ inches at level of angle of scapula. Right, 13 inches at corresponding level.

On July 1st, continuous dulness was noted to crest of ilium and marked bulging of left hypochondrium. Slight enlargement of inguinal glands. Patient died on August 18th.

On post-mortem examination it was found that the diaphragm on the left side was pressed up to the third intercostal space, and on the right to the fourth space. Lower surface studded with cancerous nodules. Left hypochondrium filled with a cancerous mass involving the upper two-thirds of the kidney and the left lobe of the liver, the tail of the pancreas, and the lower lobe of the left lung.

Fig. 5.—Melanotic Sarcoma of the Lungs. × 200.

Case IV. *Epithelioma of Tongue and Lungs.*—D——, aged forty, male, entered hospital in December of 1877, for cancer of the tongue, supposed to be due to smoking. Half of the tongue was removed in March, 1878, after ligature of both lingual arteries. The patient survived only three months, dying of exhaustion. At death epitheliomatous nodules were found in the lungs.

Case V.—G——, aged sixty-three, male, entered the hospital in January, 1878, for cancerous stricture of the œsophagus, which was treated by œsophageal bougies with relief to his pain. Death occurred from exhaustion six months after admission to hospital. Disease extended into lung, causing pulmonary gangrene.

Case VI. *Central Osteo-sarcoma of Femur, Cranium, and Lungs.*—W——, aged thirty-eight; carpenter; was admitted to hospital November 14, 1876, for central osteo-sarcoma of the left femur. The thigh was amputated a few days later. The patient made a good recovery, and in less than two months left the hospital with his wound entirely healed. He was readmitted, however,

three months later, suffering from dyspnœa, cough, and night-sweats. There was now a tumor of the frontal bone. On physical examination, dulness was found at the right apex. Temperature about 100° F. Signs of bronchitis. The patient's condition became rapidly worse, the pulmonary consolidation increasing. Death took place from exhaustion about twenty-one months after the disease began in the thigh.

On post-mortem examination the lungs were found filled with sarcomatous nodules, varying in size from a cherry to a child's fist. The largest nodule occupied the left side of the pericardium and extended into the left lung. All of the tumors had a peripheral zone of pinkish-gray color, enclosing a soft yellowish-gray friable centre. Some contained calcareous matter, some fairly formed bone. The tumor of the cranium occupied the entire thickness of the frontal bone, and was adherent to the dura mater. It presented the characteristic appearance of an osteo-sarcoma (see Fig. 3). None of the other viscera were affected, so far as was determined by the post-mortem examination.

Case VII. *Cysto-sarcoma of Gluteal Region and Lungs.*—N. Y——, aged twenty four, male; teacher; was admitted to hospital June 2, 1877. About four months previous to admission the patient noticed a small lump below the crest of the right ilium. The tumor, which had grown to the size of a cocoanut, was removed by operation, but recurred twice in close succession, and in November of the same year, about nine months after the first tumor was noted, the lungs became involved. There was high fever, rapid respiration, and pain in the right side, suggestive of lobar pneumonia. On physical examination bronchial breathing and voice were noted over the lower lobe of the right lung, posteriorly. Dulness on both sides posteriorly, but most marked on the right. Temperature rose to 104° F. Sputa contain streaks of blood. The patient recovered in part from the pulmonary symptoms, but died of exhaustion about eleven months after the growth was first observed.

The sarcomatous growth infiltrated and distended the lower lobe of the right lung and the liver. The disease had originated in the crest of the ilium.

Case VIII. *Sarcoma of Tibia, Lungs, and Spleen.*—H——, aged thirty-seven, widow; was admitted to hospital February 11, 1878, for tumor of the left tibia. A growth had previously been three times removed from the gluteal region within two years. On physical examination dulness was heard on the right side, with bronchial breathing. Absence of respiratory murmur. Patient died about twenty-eight months after the disease first appeared. At post-mortem examination both lungs were the seat of large sarcomatous nodules. The spleen was also involved.

Case IX. *Post-peritoneal Sarcoma.*—H——, aged thirty-eight, clerk; was admitted to hospital November 19, 1882. Patient was feeling well until six weeks before admission, when he was seized with violent pains in the left hypochondrium, so severe as to cause faintness. The pain afterward moderated, but has continued without intermission. Pain is aching in character and increased by standing. Has had two attacks of præcordial pain, and has passed two clots of blood from the urethra. On physical examination a tumor was discovered in the epigastric region. Its upper border appeared to be adherent to the left lobe of the liver, extended an inch and a half below the umbilicus and three inches to the left of it; slightly to the right. Left epididymis appeared to contain a nodule. At times he vomited bloody matter. About three weeks after admission had copious hæmoptysis, and until death subsequent attacks of milder character. About seven weeks after admission there was found at the right apex loss of voice and prolonged respiration. No râles. Just before death there was pulmonary œdema. At post-mortem examination, a round, nodular mass the size of a cocoanut was found firmly attached to the lumbar vertebral column and extending to the left. Liver contained about ten secondary nodules, most of them projecting above its surface. On cross-section these nodules presented a mottled appearance, owing to excessive vascularity and recent hemorrhages; were soft and friable. They were not surrounded by a well marked capsule. The mass was attached to left kidney and ureter. Atrophy of kidney from pressure and dilatation of pelvis, owing to pressure on ureter. All lobes of both lungs studded with nodules of various sizes. Largest about the size of an English walnut. Bronchial tubes contained large quantities of bloody and frothy mucus. In small intestine one secondary nodule the size of a bean.

Case X. *Melanotic Sarcoma of Left Thigh and Left Lung, Pleura, etc.*—M. D——, aged twenty-eight, widow; was admitted into hospital July 2, 1887, saying that three weeks before admission she had felt stitching pains in the left side. Slight dyspnœa.

On inspection of thorax, retraction and flattening of left chest, and bulging of the right. Left measures 17 inches; no expansion. Right measures 18; expansion, ¼ inch. Dulness over all of left lung; both bronchial breathing and voice at apex. No râles. Toward base diminished respiratory sounds and voice. At angle of scapula œgophony. Temperature, 100° F.; pulse, 100.

It was soon observed that the patient had a large immovable tumor of the upper and inner side of the left femur, causing great pain and obturator neuralgia. Diagnosis made of sarcoma of femur and lung.

Two months after admission further retraction of chest was found, both right and left measuring now only 16 inches. Area of dulness in left side complete posteriorly. Egophony at ninth space on right side. Voice and breathing present below ninth rib. On left side posteriorly there is bronchial voice and breathing, and a whistling expiration over the whole supra- and infra-spinous regions. In infra scapular region the breathing is feeble; voice normal but feeble. Two inches above angle of scapula there is egophony. No râles. Anteriorly there is pulmonary resonance in left infra-clavicular space, with dulness in second and third interspace. Below this is tympanitic resonance. On right side there is dulness from fifth to eighth ribs.

Some months later the patient died of pulmonary œdema.

At post-mortem examination it was found that the left pleural cavity was obliterated by a mass of small growths varying in size from a walnut to a hen's egg. The inferior lobe of the left lung was the seat of one large tumor. The left lobe contained a few small tumors. The right lung exhibited a peduncular tumor on the surface.

In the left inguinal region was a growth the size of a man's fist, connected by a cord (lymphatic?) (which passed under Poupart's ligament) with a larger mass that was imbedded in the muscles of the thigh, and was joined with a third mass that lay close to the femur, but was not connected with it.

The last-named mass had a gritty feel, as if it contained fine sand; the other growths were soft and gelatinoid. On microscopical examination the gritty particles were found to consist of lime carbonates, but had no true bone-tissue in them. The tumor was classed under the melanotic sarcomas (Fig. 5).

Case XI. *Sarcoma of Bones and Lungs.*—J. L——, aged twenty-two, laborer; was admitted to hospital for a tumor at the juncture of the upper and middle third of the humerus. The growth gave pain, but no glands were involved. The operation consisted in enucleation without amputation, but the disease returned, at first in the bone, later in the scapula, again in the cicatrix, and finally in the lungs. Death occurred from exhaustion, four years after the disease first made its appearance.

Case XII. *Sarcoma of Breast and Lungs.*—M. H——, aged forty-three, female, was admitted to hospital in July, 1889, for a tumor of the breast. Five years previously she had noticed a hard lump just above the left nipple, and it gradually increased in vol-

nme until it softened and broke down in spots, sloughing and giving forth an offensive odor. On admission the tumor measured eighteen inches over greatest convexity. The operation was successful, though in the autumn a nodule appeared in the cicatrix, which in four months was as large as a child's head and connected to the body by a thick pedicle. Removal on March 4, 1881. Patient died in March, 1881. At autopsy the lungs were found to contain sarcomatous nodules varying in size from a pea to a horse chestnut. Similar tumors were also found in the inguinal region, and in the brain. Curiously, in the brain the cells of tumors were round, in the inguinal region spindle-shaped. Sometimes the recurrence is of this character, as I have already stated.

17 East Forty fourth Street.

REMARKS REGARDING STRICTURE OF THE URETHRA IN THE MALE.[1]

By HOBART CHEESMAN, M.D.,

new york.

I do not expect to entertain you with any new ideas, nor to add to your stock of knowledge, but although the subject is trite, it may furnish an interesting theme for discussion. If the past few years can be said to have witnessed an epoch in surgery in general, the remark would seem no less true of that part to which my subject refers, a result which, it appears to me, is due to Dr. Otis, more than to anyone else, at least in this country.

It matters little how Dr. Otis's efforts were first directed in the course he so confidently and persistently pursued. He is at last able to rest in the assurance that the principles he has taught are generally accepted, and their logical application to practice well worked out and widely in vogue. The results, surely, are such as reflect credit to the profession, which now, for the first time, counts this one among the few of the many ills of the flesh over which it confidently asserts its mastery.

Although he may sometimes have cut the urethra too much, and perchance mutilated the meatus, and have been guilty of other surgical faults here and there—perhaps insisted too much on the importance of spasm in deep stricture, yet the critic who can see nothing in the results of his teachings except such accidental errors, committed in developing and applying them, either does not care to do him justice, or else altogether fails to apprehend the true significance of his work.

It has seemed to me a worthy object of admiration, and a remarkable proof of the versatility of certain distinguished critics, and of their capacity to make the most of small opportunities, that it has been found possible to induce such an amount of service in the rôle of terrible example and in the awful part of medical bugbear, from the few unfortunates of this kind which have been constantly passed around the circle. Like the stage army, ten have become ten thousand by diligent marching around in grave and imposing file. Personally, I have happened in practice to meet with but very few mutilations of the meatus (and none of the urethra) from excessive cutting, and these were seemingly chargeable to excessive zeal on the part of apprentices rather than to Otisism proper.

We may better appreciate the work of Dr. Otis by reference to the state of the subject at the time he began it, comparing that with the present, and observing, at the same time, how development has followed the course he first indicated. Then stricture of the urethra was a stumbling-block—practically admitted as incurable; now no competent surgeon despairs of curing the very worst cases. What has led to this rapid and remarkable revolution?

One of the most important steps was to get definite knowledge of what constitutes stricture. This implied a preliminary understanding of the nature and size of the normal urethra. Sir Henry Thompson, in 1869, gave the following directions for exploration of the urethra for ascertaining the presence or absence of stricture: "A flexible bougie of medium size, that is, No. 7 to 9 of the English scale (16 to 18 French), is to be used, while as to form it should be slightly curved and blunt, not conical, at the point. If a small instrument is employed it might pass through the stricture without giving any sign of its existence, and so fail to detect it; but if a No. 8 bougie (17 French) passes easily into the bladder we may be satisfied that no stricture, or at most a very slight contraction, exists." Dr. Otis quoted this passage, in 1874, then recognizing and pointing out the errors, just as everyone recognizes them to-day.

Very naturally, strictures after treatment founded on such nebulous notions returned, or rather remained; for stricture does not recur, it remains. Dr. Otis began by ascertaining the calibre of the normal urethra, and a natural and sensible beginning it was. We are all now working approximately on the basis of his demonstrations, as a matter of fact, and find his rule for estimating the size of the urethra in particular cases sufficiently reliable for practical purposes. (Since reading this paper I have read the recent paper on stricture by Professor White, of the University of Pennsylvania, who, in referring to this point rather critically, concludes by recommending the following scale, and thus in the most emphatic way possible admits the essentials of Dr. Otis's teachings. He says: "The scale which I have adopted for use is as follows: A penis of three inches in circumference, at the middle of the spongy portion, indicates a urethra which should normally admit an instrument of about 26 to 28 mm. in size; when $3\frac{1}{4}$ inches, 28 to 30 mm.; $3\frac{1}{2}$ inches, 30 to 32 mm.; $3\frac{3}{4}$ inches, 32 to 34 mm.; 4 inches, 34 to 36 mm., beyond which size it is seldom necessary to go." I do not think that Dr. Otis himself would cavil very much at this, and it seems to me to represent pretty accurately the prevailing criticism of his teachings—the deed affirms what the word denies. Compare these rules of Dr. White with those of Sir Henry Thompson quoted above, and the point is evident. The difference involves the potency of all important advances recently made in urethral surgery, as well as much that relates to the organs beyond. No more substantial evidence need be asked of the truth and potency of Dr. Otis's teachings than is found in Bigelow's operation of litholapaxy. The well-informed are now aware that the middle portion of the pendulous urethra is narrower than the other portions, with the exception of the isthmus and meatus perhaps, and that there are also normally minor undulatory variations, as first demonstrated by Sands and Weir; but we need not fail to make due allowance for all important and lately revised facts in explorations for stricture, in order not to detract from what is important in the teachings of Dr. Otis; facts easily explaining the difference between his and Dr. White's scale.) To resume: Dr. Otis, for the first time, made it possible to determine with accuracy the presence or absence of stricture, and to locate it with precision, and consequently to know just how much a cure in a given case implies—to know when a cure is effected and when not.

Although certain Frenchmen had already called attention to the influence of anterior stricture in producing deep spasmodic stricture, which latter condition they maintained had generally been mistaken for organic stricture, and in this way accounted for the large proportionate number of deep strictures which had, until then, been taught to exist; yet these ideas had not found much encouragement until Dr. Otis, recognizing their importance, proved and ably taught their validity, against much opposition, as is well known.

Organic stricture is now recognized, at least by many, as most frequent in the anterior urethra, where the causes producing it operate most frequently and most intensely.

[1] Read before the Manhattan Medical and Surgical Society, January 3, 1891.

Knowing now just what was involved, the way was clear for the first time for solving the problem of successful treatment. Dr. Otis early demonstrated the curability of organic stricture, inventing the instruments still regarded by many experienced surgeons as best adapted, and teaching their proper and skilful use. Others have no doubt largely contributed directly in working up to present conditions, as well as indirectly, in checking extravagant tendencies and correcting errors of various kinds and degrees liable to be committed under the circumstances. Still, whatever credit may be due others, Dr. Otis, I think, must be regarded as the man of the epoch. Had he not lighted and paved the way, perchance we still were grouping in the murk and mire of twenty years ago. Surely few will now be found, so unappreciative as longer to affect to ignore the importance of his influence, or so oblivious as honestly to protest while unconsciously guided and benefited by it. Each surgeon may have his own peculiar notions, and each may lean to some pet scheme of practice. But all in act, if not in word, now admit the controlling influence of his ideas, and any method of practice must be based largely upon them to complete successfully, although not necessarily following his in detail. Whether or not Dr. Otis accepts merited modifications and corrections of his teachings, or whether or not he follows the conservative rules of practice now in favor, with more facts and experience before us, is of no consequence, as effecting the large part he has had in bringing the issue.

The writer is convinced (with which most will presumably agree) that a very large majority of strictures can be cured by the method of gradual dilatation after all strictured tissue in the sensitive region at and near the meatus has been thoroughly divided. Without this preliminary operation, when indicated, attempts at gradual dilatation are about useless. The peculiar sensitiveness of this region probably accounts for this, attempts at stretching only exciting more irritation in the part and corresponding reflexes in the deep urethra. The region of the meatus we know is by far the most sensitive; the telegraphic centre, it has been called, of the genito-urinary system, which is in intimate nervous relations in more respects than one with the region of the deep urethra, the next most sensitive part. Possibly the sphincter element existing to a slight degree in the meatus, analogous to that of other discharging orifices, as for example, the anus and vagina, may increase its resistance to efforts at dilatation. Whatever the true theory may be, when all strictures or contractures in this region have been thoroughly divided, then, and then only, success in treatment is easily possible, in ordinary cases, by gradual dilatation.

The meatus is now acknowledged to have its proper and important function. This is to mould the stream of discharging urine to proper form, and to serve as a point of elastic resistance to the force behind, by which the stream may be projected to a convenient distance. The meatus, therefore, should not be mutilated so as to impair this function. This can always be avoided by subcutaneous incision of any stricture-tissue existing, the cutaneous orifice being divided only sufficiently to permit when healed its free expansion, by a forceful stream of urine, to a size equal to the full size of the stream capable of escaping through the normal membranous urethra. Conditions should be such as to permit free and unconcerned relaxation of the membranous urethra during the act of urination—a perfectly passive state. The active function of this and the prostatic urethra is normal retention, the muscular tissue being kept for this purpose in a state of tonic contraction. In voiding urine, so long as the stream in front of the isthmus finds a smooth and capacious channel and free vent at the meatus, all goes well. But whenever it encounters obstruction the impinging portion is deflected, and consequently interferes with the otherwise unhindered portion by throwing the whole stream into confusion, and thus only a small jet may escape through a stricture of considerable calibre. The normal urethra being a delicately pliable sheath, the portion behind an obstruction, situated anywhere in the penile portion, but most especially at the meatus, must be painfully distended and irritated by a stream flowing from the bladder with natural force and volume.

The membranous urethra alone is capable of preventing this, by contracting sufficiently to reduce the stream to the required limits, or rather, by holding itself suspended, suitably, between its naturally closed condition during normal retention, and its other natural state of unconcerned dilatation while the bladder is being emptied. But this act is an unnatural one, and the effort injurious to the parts, as may be witnessed by trying the experiment while voiding urine through a healthy urethra. The watchful readiness of the membranous urethra to protect, in this way, the inflamed or sensitive portions in front of it, may also be observed whenever concentrated and scalding urine is about to escape through a healthy urethra, in the reluctance and hesitation with which the stream is allowed to start, and in the tendency to shut it off when it reaches the tender region of the meatus. Such disturbances, long continued, must lead to confusion of function and result, at last, in organic changes. The signal for free relaxation, being now constantly associated also with efforts at contraction, perchance, at last ceases to excite any other, and then we have abnormal retention from spasmodic stricture. No doubt, also, in time the mucous membrane of the deep urethra may become inflamed, and consequently infiltrated with inflammatory products from this cause alone, resulting at last, possibly, in organic stricture. Extreme sensitiveness is not the only reason apparent why an obstruction at the meatus, more than elsewhere, is capable of irritating and consequently of exciting spasmodic stricture in the deep urethra. The meatus is situated farthest from the deep urethra, the capable source of protection without whose vigilant activity the whole penile urethra must be exposed to the full contracting force of the bladder, acting through the column of urine obstructed at the meatus. The effect of this will be better appreciated by recalling the law of physics, that pressure on a column of fluid is transmitted in every direction with a force equal to that applied to any portion of it. There is another kindred occurrence in this connection. Portions of the stream of urine impinge upon the mucous membrane covering the stricture behind, then being deflected, throw the whole current into confusion, and this, in addition to stretching, constantly irritates by friction, and might, I should think, lead to erosions and become an important factor in augmenting the already existing stricture. Thus the theory of this form of spasmodic stricture seems rational, and it is evident how stricture, or simple contracture, of the meatus may give rise to symptoms otherwise apparently disproportionate to the cause, even so remote sometimes as to go unrecognized until by removal of the cause the symptoms disappear. The importance becomes evident of thorough division, always, of strictures in the region of the meatus, as a preliminary and aid to the cure of those beyond.

Theoretically, the meatus requires enlargement whenever it does not easily dilate for the passage of a bulbous explorer, fit for the normal relaxed membranous urethra, in the given case It may be entirely free from inflammatory deposit, or thickening, and small from encroachment of its cutaneous substance only, most likely congenitally. On the other hand the orifice, on inspection, may appear of sufficient size, but oppose the passage of the full-sized explorer, because of inflammatory deposits, when instead of a thin, soft edge of tissue stretching over its bulb, there is apt to be present a more or less thickened ring, not easily stretched. Frequently stricture is found just within this portion, maybe, more or less continuous with it. Another very frequent site for stricture is at, or just beyond, the deep end of the fossa navicularis. These conditions may be found in various degrees, singly or combined. Besides being subject to congenital contracture, the meatus and contiguous urethra are exposed to a

greater variety and degree of influence liable to lead to inflammatory thickening than any other portion of the urethra. It is not surprising, then, that one should find very many meatuses requiring preliminary enlargement, in treating strictures, without necessarily meriting the odium of hobbist. I do not mean to be understood as claiming that every case, or even a majority of cases, require meatotomy, nor of those requiring it that very many excite spasmodic stricture; but that this is possible and more frequent and more important than is generally admitted.

Strictures found at or within an inch, or even more, of the meatus, are easily divided with a blunt-pointed bistoury, under local cocaine anæsthesia, although, as a matter of fact, more painful than the division of strictures farther down in the less sensitive parts, unless the latter be dense and extensive, necessitating painful stretching with the dilating urethrotome. This done, when indicated, most strictures met with in private and dispensary practice can be satisfactorily treated, as already remarked, by gradual dilatation; may be cured, and that too, more expeditiously than is believed by some. A comparatively few cases only have strictures so dense or extensive or so tight as to render this method ineffective. They are doubtless most frequently met in hospital wards. Wherever encountered, they are, I believe, best treated by the use of the dilating urethrotome, or this in conjunction with Maisonneuve's, if not deeper than the peno-scrotal junction; deeper than this, by external urethrotomy; unless the latter rather formidable operation for deep passable stricture shall soon be superseded by the simpler one of internal urethrotomy, combined with artificial drainage through the perineum, as practised by McBurney at Roosevelt. The gravest danger threatening from the deep internal operation, as first practised by Otis, arising from septic absorption, ought to be obviated by artificial drainage of the sagging segment of the wounded urethra, the anterior segment finding natural drainage by gravitation through the meatus, and the very deepest into the bladder. Of course it cannot take the place of external urethrotomy for impassable stricture, or for those through which Maisonneuve's guide cannot be made to go, nor for some cases of passable stricture complicated with abscess or extravasation of urine and the like.

But it has been my experience that strictures have a tendency to return after urethrotomy to their former state, to a greater or less degree, unless the passage of sounds is employed for a considerable time after the operation. The cutting appears to hasten the resolution, probably in a way analogous to that observed after operation on the hardened and hypertrophied tissue from old laceration of the cervix uteri. Dividing the stricture of the urethra does not alone, however, seem to insure the completion of the process, but several weeks' use of full-sized sounds is necessary, in most cases, to complete a permanent cure.

The following cases are selected to illustrate some of the points which have been dwelt upon:

Case I.— A student, aged twenty-one, denied having ever had any venereal disease, or sexual intercourse. For ten days had been suffering from an attack of bilious diarrhœa and occasional vomiting, accompanied by various nervous symptoms, such as pricking sensations over the body and cold and blue extremities, and at times chilly tremors in the back. During the last thirty-six hours had been unable to pass a drop of urine, while at stool even. The urine had been drawn by his physician through a soft rubber catheter. The meatus admitted snugly a No. 20 French bulbous exploring bougie; looked rather red, but was without inflammatory thickening. A steel sound, No. 22 French, also passed into the bladder, being mildly grasped in passing through the membranous urethra. The urine was then readily drawn with a No. 20 French soft catheter, and subsequently found to be normal, except for the presence of a trace of albumin. The retention of urine continued unaffected, although all the usual means of relief in such cases were employed. At the end of ten days after first seeing the case, not a drop of urine having been passed except through the catheter, I incised the meatus so as to admit the passage of a No. 30 French bougie a boule, which could then also be passed to the membranous urethra and withdrawn without obstruction. The next day urine was voided, for the first time in three weeks, at stool, and on the second day it was being passed freely and regularly. The patient continued perfectly well from that time for two months, since when I have not seen him.

Case II.—Produce merchant, fifty-eight years of age. Had several attacks of gonorrhœa in youth. The last attack was twenty-five years ago, since which time he has always suffered more or less from gleet and frequent micturition, and passed a small stream accompanied at times with pain. During the past year has had to get up about every two hours at night to urinate, and during much of this period the act has been accomplished only after much straining and by driblets. This was his condition when first seen. Examination of the urine showed nothing abnormal except a moderate excess of mucus. No prostatic trouble could be detected. No. 22 French steel sound passed snugly through the meatus and six inches down, and was there arrested. No. 18 passed seven inches, but would go no farther. After many futile efforts to enter the bladder, finally a fine whalebone was manœuvered in by passing it down alongside of a No. 4 elastic bougie. Two days later the same efforts were made and with the same results, and a third time, after waiting two days longer, hot sitz baths and the other conventional measures of relief having been employed all along. A No. 18 steel sound could be passed six inches easily, and urged an inch deeper, where it was firmly grasped and held, defying all efforts to get it further short of extreme violence. Attempts were made by several surgeons, but with the same result. The meatus was then incised so as to admit a 34 steel sound, Nos. 18, 22, 24, and finally 27 steel sounds then passed in succession into the bladder, after being held for a moment in the grasp of the membranous urethra. The next day Nos. 27 and 29 passed easily and entered the bladder, and the patient declared that he had urinated but twice during the night, instead of five or six times as previously. Ten days later No. 30 sound was being passed easily, although still slightly grasped in going through the membranous urethra. The patient had been voiding urine about once in four hours for several days. Passed in my presence, the stream was normal in all respects—full, strong, and uninterrupted. He remained under observation for six weeks more, and had no further trouble.

Case III.—An out-of-town drygoods merchant, aged forty-eight, denied all venereal diseases; came with a note from a neurologist who stated that he had been treating the patient for neurasthenia, but had concluded that probably the origin of his trouble was in the urethra. His symptoms were insomnia, occipital headache, pain in the back of the neck and lumbar region, of dull heavy character; also sciatica, pain in the perineum, and on micturition, especially at the neck of the bladder and at the head of the penis. He suffered from frequent micturition, also passed a small and feeble stream; felt weak and tired all the time. He was married, but had not been able to have sexual intercourse for two years, not even an erection; had no nocturnal emissions, but every few days he passed a large quantity of what appeared to be seminal fluid while straining at stool, which was sometimes bloody. Pain in and about the anus caused him to imagine that he had internal piles, but this did not prove to be the case, nor did the prostate prove to be enlarged, although pressure over the region caused pain. The penis corresponded in size to an urethra of 32 French calibre, but appeared pale and lifeless. The meatus admitted No. 24 French, was red and pouting and very sensitive, as was the whole urethra, a rather soft gum elastic bougie causing much pain, especially in passing the deep urethra, and considerable bleeding from this region, although used with the utmost gentleness.

The meatus was cut to full size, and in a few days, when it had healed somewhat, exploration of the urethra revealed no obstruction beyond. Through Sturgis's short endoscope the urethra appeared abnormally red all the way down, and in the deep parts a granular condition was seen, bleeding easily. By means of a cotton applicator, nitrate of silver, twenty grains to the ounce of water, was applied to these granulations. Two days later, and from that time onward for three weeks, steel sounds were passed into the bladder every two days. At the end of this time a 32 French sound was being used, causing not much unusual pain, and no more bleeding, and the urine was being voided less frequently and in a good stream. The insomnia and other nervous symptoms had abated. He was, for the first time in two years, having erections in the morning, and had ceased to have seminal discharges while straining at stool. He was obliged on account of business to return home at this time, and to the care of his former physician, who was to continue the use of sounds. I see no reason why he should not have got entirely well under this treatment, and I am not sure that he might not have recovered in time after the stricture of the meatus had been cured, without any other local treatment, believing as I do, that this was the original cause of all the trouble.

Case IV.—A commercial traveller, aged thirty, married. Had several attacks of gonorrhœa, the last one six years ago. Had suffered from gleety discharge and other symptoms of stricture ever since. Had been treated for it in London and in this city, without permanent benefit. He was worse than ever before, suffering from painful and difficult micturition, being obliged much of the time to strain out the contents of his bladder in driblets. Rest at night was broken, and he looked anxious and exhausted, and declared himself unable to attend to business properly.

The lips of the meatus were thickened and red, the orifice was contracted, there was stricture behind it all along the first inch, and at three and a half inches a hard, nodular enlargement of the urethra, which permitted with difficulty the passage of a 15 French steel sound. There were other minor strictures. The strictures at and near the meatus were divided with the bistoury, the largest sound possible was passed through the nodular stricture, at three and one-half inches, which was then manipulated gently for two or three minutes over the sound so as to stretch the stricture. This operation was repeated every two or three days at first. At the end of six weeks the nodules had entirely disappeared, and at the end of ten weeks a number 32 French sound was being passed into the bladder, and the bulbous explorer detected no stricture anywhere. At the end of three months the patient was discharged cured, and has continued so for more than two years, without the use of sounds, except on two or three occasions, when one has been passed only to detect any signs of recurrence, but none has appeared. This was a case in the beginning which might have been very rationally regarded as requiring urethrotomy, but the result shows the possibilities of gradual dilatation when practised persistently after free division of strictures at and near the meatus. The patient stated that in several former attempts at gradual dilatation which he had at different times submitted to for long periods, the strictures at the meatus had not been incised, but that the attempt had been made to dilate them with those farther down, the result being as described above, no more than very temporary relief.

Conclusions.—1. Dr. Otis has been the controlling spirit in urethral surgery in this country during the epoch.

2. Its present issue is the legitimate result of the development of his ideas, largely directed and impelled by his personal efforts.

3. His scale of urethral calibre, modified to suit local variations, is approximately true and a reliable practical guide in detecting stricture.

4. His teachings respecting stricture at the meatus and spasmodic stricture of the deep urethra contain important truth, not safely ignored in practice.

5. As encountered in ordinary practice, stricture is much the most frequent in the penile urethra, where the causes producing it operate most frequently and intensely.

6. A large majority of strictures can be satisfactorily treated by gradual dilatation, combined with meatotomy when indicated, including in this term division of all coarctations within the first inch of the urethra.

7. Meatotomy is indicated when the orifice is smaller than the normal calibre of the membranous urethra in the given case, or when it is inelastic.

8. Smallness of calibre of stricture alone does not render urethrotomy necessary. On the contrary, any passable stricture of soft and yielding character, except at the meatus, may be cured by gradual dilatation; but when strictures are dense or very extensive, or stubbornly resistant from any cause, urethrotomy is indicated, and may be justified in many cases capable of dilatation, in which to save time is important.

9. Internal urethrotomy should be employed in front of the peno-scrotal junction, and not beyond this point, unless the sagging segment of the urethra be provided with artificial drawage; otherwise the external operation should be performed.

10. Impassable stricture and certain complicated passable ones necessitate the latter operation.

11. The use of sounds is required for a considerable time after urethrotomy to insure complete cure.

DRAINAGE IN ABDOMINAL SURGERY.[1]

By DUDLEY P. ALLEN, M.D.,

visiting surgeon to lakeside hospital and charity hospital, consulting surgeon to city hospital and st. alexis hospital, cleveland, o.

Mr. President and Fellows of the Academy: In beginning this paper I wish to express to the Fellows of the Academy my appreciation of the courtesy extended to me in the invitation to discuss before you so important a subject as that of drainage in laparotomy. Within the limits of a short paper it will be impossible to cite statistics or quote surgical opinions. It may not, therefore, be improper to say that the opinions here expressed are the product of repeated opportunities of observing the methods employed by many of the most noted operators, both of this country and of Europe, together with the author's personal experience. The subject will be discussed under three heads:

I. Is drainage of the abdomen after operation ever desirable?

II. If desirable, in what cases should it be employed?

III. When employed, what method should be used?

In discussing the first proposition, it is not impossible that the same principles which hold good in the treatment of wounds in general may be found true of wounds in the abdominal cavity. To my mind the principal factors in securing union of wounded surfaces are: 1. That they should be aseptic. 2. That they should be brought into and preserved in close apposition. 3. That the accumulation of secretions between these surfaces, and their consequent separation should be prevented.

That wounds should be preserved aseptic is a proposition which will be accepted by all, and demands no consideration.

That wounds should be kept in close apposition is a proposition equally accepted, but often it is not put into practice. In the amputation of extremities, and in the extirpation of mammary tumors, it was formerly almost the universal practice to insert drainage-tubes. I presume in these and all kindred operations the use of the drain-

[1] Read before the Section in Surgery of the New York Academy of Medicine, May 11, 1891.

age-tube has greatly diminished. For my own part, I very rarely use it, seeking, in amputation of the breast and of the limbs, to stop all oozing before closing the wound, to keep it strongly pressed together during the insertion of sutures and applications of dressings, and by the pressure of the dressing so to hold the surfaces in apposition as to obviate the collection of secretions. By this method the rule is to secure union by first intention, without the drainage-tube. The same conditions exist to a degree in the abdomen which are present in other wounds. That there is considerable pressure within the abdominal cavity, and that its surfaces come into close contact, is, I think, evidenced by the fact that in attempting to insert the hand into the abdomen, especially if the anæsthesia is not complete, the omentum and the intestines insert themselves between and separate the fingers in spite of the operator's strongest efforts to prevent it. In operations for perityphlitis I have opened abscesses reaching from Poupart's ligament to the liver, containing large quantities of pus, washed them, and packed them with gauze, and have been surprised at the first dressing to find the degree to which the intra-abdominal pressure had tended to extrude the dressing, and the small amount of packing which could be reinserted. Notwithstanding, however, the close apposition which exists between the abdominal viscera, on account of the intra-abdominal pressure produced by the tonicity of the abdominal wall and the distention of the intestines by gas, accumulations of fluid take place in the abdominal cavity. A common instance of this is ascites. In operating for stabs of the abdomen, I have removed large quantities of blood from the abdominal cavity coming from wounds of the internal epigastric artery. Doubtless after laparotomy fluids may collect in the abdominal cavity in spite of the apposition of surfaces and the existing pressure; but I strongly suspect that this occurs chiefly where there is bleeding from vessels of some size, or where the pre-existing condition of the peritoneum is such as favors the pouring out of fluid. My observation would lead me to doubt whether the collection of fluid is, as a rule, great under other circumstances, unless sepsis be present or strong antiseptic solutions be employed. While, on the one hand, it must be acknowledged that by apposition and pressure we cannot escape the collection of fluids in the abdominal cavity to the degree which may be done in wounds more subject to pressure; on the other hand, the lining membrane of the abdomen is especially able by its power of absorbing fluids, to care for and remove accumulating secretions. That the peritoneum is able to absorb fluids is shown by the disappearance of ascites, and by the disappearance of fluids, which can be demonstrated to collect at times in connection with strangulated hernia. In cases of intestinal obstruction, where immediate operation has been declined, I have been able to demonstrate the presence of considerable quantities of free fluid, and a day or two latter, when the operation has finally been undertaken, have found that this has entirely disappeared, with nothing but plastic lymph gluing together the intestines remaining. The same ability of the peritoneum to absorb fluid has been demonstrated by injections made into its cavity.

If, then, there are certain forces tending to restrict the accumulation of fluid in the abdominal cavity, and there is also a well-marked force for removing such accumulations when they occur, the question arises, What fluids may safely be left in the abdominal cavity to be cared for by natural means, and what ones must be artificially removed?

Those fluids which can be safely left to care for themselves, it seems to me, are, 1, serous oozing from wounded surfaces, and 2, small amounts of blood collecting from the same sources. Those which would be dangerous to leave are, 1, large amounts of blood, and 2, septic or infectious material.

That collections of serum are readily absorbed from the abdominal cavity is unquestionable. I believe the same to be true of small collections of blood. It is difficult to demonstrate this in the abdominal cavity, but if it occurs elsewhere it is reasonable to suppose that it may take place here. When an assistant in the Massachusetts General Hospital, I saw a case of secondary hemorrhage of the femoral after amputation, on account of the early absorption of too slender cat-gut. When the wound was torn open it was found aseptic and containing a large clot, almost entirely separating the flaps, but undergoing organization. All of us have seen healing by Schede's blood clot. In tuberculosis of the extremity of the femur I have removed the entire interior of the epiphysis excepting the bony shell of its exterior, packed it with iodoform gauze, a few days later irritated the interior of the bony cavity so that it has bled sufficiently to fill this cavity, covered the opening into the bone with a small piece of oiled silk, dressed the whole with a permanent antiseptic dressing, and seen complete closure of the wound without a drop of secretion and with entire restoration of function of the knee. If this can occur in an amputated extremity, and in the interior of bone, I see no reason why the same cannot take place in the abdominal cavity. Beyond question, however, the leaving of large amounts of blood to become organized is fraught with danger, since blood-clots seem particularly susceptible to infection and decomposition; also patients weakened by the loss of blood have less power to resist a slight degree of infection, which they might do under more favorable circumstances. While on the one hand the leaving of large amounts of blood in the abdominal cavity is to be deprecated as a source of danger, I doubt if small amounts are of so serious consequence as some have believed, provided there is no infection.

The question now arises, Have we means of drainage which are efficient in removing fluids which may collect in the abdominal cavity? Experiments made upon dogs and cadavers would indicate that fluids injected into the abdomen, through tubes placed in the pelvis, are not drained away by the same. I have repeatedly thrown fluid into glass drainage-tubes placed in the abdominal cavity, in dressing cases after laparotomy, and found that it did not distribute itself, but remained at a constant level in the tube. Personally, I have been surprised in many cases where I have used the drainage-tube to find how small an amount of fluid escaped from it. Doubtless there are cases in which the amount of fluid drained away from the abdomen is very great. Ten or twelve years ago I remember Thomas Keith, of Edinburgh, showing me many quarts of fluid which had been removed from the abdomen, by drainage, after laparotomy. I have performed laparotomy in a case of ascites, where no cause for the collection of fluid could be found, and where the woman recovered rapidly from the operation and was sent home, and remained to all appearances well for several months; where, at the expiration of this time, the abdomen again became distended by fluid, opened itself at the umbilicus, and discharged a large patent pailful of serum—to heal up again by the simple application of a pad of cotton by means of adhesive plaster. Though I cannot demonstrate it to be a fact, I strongly suspect that cases in which large amounts of serum have been removed by the drainage-tube are those in which there was a tendency of this fluid to accumulate before the operation, and that the fluid is not the product of divided adhesions.

Cases in which Drainage should be Employed.—To pass, then, to the second part of our paper: In what cases shall drainage be employed? Evidently it will be impossible to discuss all conditions which may arise. We may, however, discuss those which are most common. Perhaps this can be done most rapidly by citing briefly, in connection with some of these conditions, a few cases.

The abdominal cavity should, we believe, be drained, 1, *in septic peritonitis*. Wherever found, septic matter should be removed, and this is nowhere truer than in the abdominal cavity. In a case of universal septic peritonitis in a sporting woman, I found pus bathing the coils

of intestine in every part, and extending from the cavity of the pelvis to the liver, the stomach, and the spleen. The abdomen was opened widely, washed thoroughly, and all pockets of pus sought out, cleansed, and a drainage-tube was carried from the abdominal wound down through the vagina. In separating the adhesions, in the region of the cæcum, a hole was torn in the ascending colon, from which there was no escape of material until about three days after the operation. Then from two to three quarts of pus and fæces were washed from the abdominal cavity twice daily, through the medium incision which had been left open. The woman completely recovered, and is to-day plying her former vocation, a picture of health, notwithstanding a very minute fecal fistula. That this and similar cases of septic peritonitis must be treated by drainage, in whatever way and direction may be requisite for its perfection, seems to me beyond question, whether such drainage be ventral, vaginal, or lumbar.

2. *In gunshot wounds* drainage is rarely indicated. In the few cases that I have seen, I have been surprised at the small amount of extravasated fecal material, even when the lumen of the gut was largely destroyed. It seems to me in these cases all that can be accomplished will be gained by thoroughly cleansing the abdominal cavity without drainage, for it will be difficult by any arrangement of drain, unless it be the tampon of Mickulicz, to procure drainage in these cases.

3. *Tubercular peritonitis* presents itself under various forms and may be operated at various stages. In some cases where the accumulation of fluid has been general, and the operation has been early, recovery has resulted from opening the abdomen, removing the fluid, and closing of the incision after having perhaps washed the cavity or dusted its surfaces with iodoform. Where I have adopted this plan, on the removal of the sutures closing the abdomen there has, however, been a discharge of re-accumulated fluid. In other cases I have found the fluid produced by the tubercular process to be contained in a cavity occupying the pelvis and the lower part of the abdomen and shut off from the upper portion of the abdomen by adhesions among the intestines, and in these cases I have washed, cleansed, and drained, and I cannot imagine that such cavities can be successfully treated in any other method than by drainage.

4. *Operations for Perityphlitis.*—Where pus is present, and where adhesive inflammations have prevented its invasion of the general peritoneal cavity drainage is of course in place. Where the infection has generalized itself over the abdomen, treatment must be the same as for septic peritonitis from other causes, and that thorough cleansing and drainage are indicated.

5. *Intestinal obstruction*, whether the result of volvulus, adhesions, or constricting bands, is, in early stages, often accompanied by the effusion of serum. Later this disappears, becomes absorbed, and there remains plastic lymph, gluing together the intestines. If operation takes place early in these cases, it is my belief that the serum is not septic and does not require drainage. The condition changes to a septic one as time advances, and if at this time the patient can endure the shock of operation, it must be accompanied by the removal of the septic material. To illustrate my meaning: I operated upon a case of intestinal obstruction thirty-six hours after its commencement, and found the case to be caused by a Meckel's diverticulum. The abdomen was filled with serum. This was washed out, but not drained, and the patient's recovery was rapid and complete. As before stated, in strangulated hernia I have repeatedly returned the gut, removed considerable amount of serum from the abdominal cavity without washing or drainage, and recovery has resulted. In other cases, where I have been called long distances into the country, and have operated very late in cases of intestinal obstruction, I have found no fluid, but the presence of plastic lymph, and with it evidences of infection. In such cases patients have died in spite of my best efforts to save them. In other cases where operation has been declined until late, I have been able to demonstrate, early in the case, the presence of free fluid in the abdominal cavity (at which time I believe operation could have been successfully undertaken), to find later, when operation was finally consented to, that this fluid had disappeared and its place been taken by plastic lymph. Although I have not seen enough of these cases to reach a definite conclusion, the impression has grown upon me that in an early stage, when free fluid is present in the abdominal cavity, they are favorable for operation, and this fluid is not septic and does not need to be drained away; whereas, later, when the fluid has disappeared, there is a deposit of plastic lymph, with adhesions and infection, rendering operation more dangerous and drainage important.

6. *Hemorrhage.*—When this occurs in considerable quantities, and cannot be controlled, it is doubtless best that it should be removed. It is my impression, however, that it is best to take good care that much hemorrhage does not occur, than to seek to escape its dangers by drainage. When it is suspected, I would prefer not to content myself with an incision which will simply admit two fingers, to work in the dark, not seeing what is being done, but to enlarge the incision, seek out the points of hemorrhage, tie the blood-vessels, or, where more convenient, control them by means of a continuous catgut suture. It is my experience that troublesome and deep hemorrhage may be admirably controlled by the continuous catgut suture, and cases must be few indeed which are not amenable to this treatment. I am not one of those who believe that a small abdominal incision is of primary importance in laparotomy. That it is desirable is readily admitted; but knowledge of what is taking place in the abdominal cavity, and certainty of the manipulations of the operator, in dangerous and uncertain conditions, seem to me to be of superior importance.

7. *Extra uterine Pregnancy.*—In operations for this condition there are cases in which it is impossible to control bleeding, and in which drainage is important. If the operation is upon the tube, which has just ruptured, or is still intact, and the tube and blood can be thoroughly removed, drainage may or may not be employed, according to the completeness of the operation. But there are many cases in which the products of the extra uterine fœtation cannot be completely removed, or in which the removal of the adherent placenta would be unwise, in which drainage must be employed.

8. *Adhesions.*—It is my belief that divided adhesions do not furnish in themselves cause for drainage. Uncontrolled hemorrhage is, as has been stated, a cause for drainage, but not the adhesions in themselves. In some cases of ovarian tumors of enormous size, where the adhesions have been universal and dense, and where their division has been accompanied by extensive hemorrhage, I have tied all bleeding points, at times applying cloths wrung out with hot water, well up to the base of the mesentery in the lumbar region, have closed the abdomen without drainage, and seen the cases make a complete and uninterrupted recovery.

9. *The Escape of Cyst Contents into the Abdominal Cavity.*—When this occurs, and is infectious, no precaution for its removal can be too great, and in addition to washing, drainage is doubtless in place. In other cysts I do not believe this necessity exists. The contents of simple ovarian cysts seem to be innoxious. I have had a large amount of fluid from a cyst of the pancreas escape into the abdomen, which has been removed by washing without drainage, in which recovery has resulted.

10. *Pyosalpinx.*—Perhaps opinion will differ more with reference to the drainage-tube in this than in any other disease. It is claimed by some that the pus contained in the Fallopian tubes varies in character, and that many cases are slightly infectious to the abdominal cavity. Until we know more, however, concerning the character of pus and the cultivation and propagation of various forms

of bacteria, we would be wise to act upon the supposition that all pus is infectious. If pus tubes can be removed without rupture, and the uterine extremity of the tube be disinfected, or seared by actual cautery, I should consider drainage unnecessary. If, on the other hand, pus escapes, or we are uncertain as to infection, or if a part of the ruptured tube should remain, it would be wise to drain, our hope being that by drainage we may remove not only infectious material, but also the fluid which would form the best nidus for its propagation. The field of operation, too, is especially susceptible to drainage in these cases.

11. *Pelvic Abscesses.*—In this condition not only should the pus be removed at the time of operation, but the escape of that which forms subsequently should be secured by means of drainage

The third part of our paper, namely, what method of drainage shall be employed, will demand but few words. Vaginal drainage, which has been much employed, is now largely discarded. The two methods now generally used are the drainage tubes placed in the abdominal incision and the tampon of Mickulicz. The former is of more universal application, being especially fitted to prevent the accumulation of fluid in the pelvis. The Mickulicz tampon is especially effective for those cases where localized septic infection takes place, as in pelvic abscess, ruptured pyosalpinx with incomplete removal, and advanced extra-uterine pregnancy.

In conclusion, I would say that the ideal laparotomy is that which closes at once the abdominal cavity. Anything which prevents this subjects the cavity to possible subsequent infection. Advance must be looked for in methods which will obviate the necessity of drainage.

INOCULATION OF A JAPANESE WITH SCARLET-FEVER GERMS.

An Attempt to Obtain a Modified Lymph to Prevent Scarlet Fever in the Caucasian.

By A. S. ASHMEAD, M.D.,

NEW YORK.

On May 17th I inoculated with scarlet-fever germs a native of Nagano-Ken, Japan, aged twenty four, three years resident in this country. There was no family history of syphilis or leprosy. The germs were taken from the desquamations on the forearm and palm of a German child, aged two years and three months, a patient of Dr. Ernest F. Ruppe. I took them on the twenty-fifth day, pursuant to a suggestion of Professor Edington, of Edinburgh. They were inserted in the left forearm. The results were as follows:

May 18th and 19th.—Headache of slight intensity; an inflamed zone about the insertion.

May 20th.—Areola of intense scarlet $\frac{3}{8}$ inch in width, completely encircled a central crust; throat and fauces very red, tongue swollen and coated, no enlarged tonsils, four serous vesicles, not of the same size, and of irregular shape, at the edge of the crust, between the latter and the areola; skin swollen about the sore; pulse, 76; temperature, 99° F.; pain and itching.

May 21st.—Vesicles drying, crust darker and enlarged, much oozing of lymph; crust elevating; uvula and fauces intensely red; pulse and temperature normal.

May 22d.—The areola still persists, much lymph oozing, much pain; no enlarged lymphatics; fauces still red; temperature, 99° F.; pulse normal.

May 23d.—Areola continues; lymph welling up beneath the crust; crust enlarged and elevating; lymph abundant, of a lighter color than before; temperature, 99° F.; pulse normal.

May 24th.—Areola still persists; a little pus, lymph plentiful, crust increased in size; pulse and temperature normal.

May 25th.—Areola desquamating; crust contracting; inflammation lessened; the redness of throat increased; tonsils enlarged, white patches on both of them; headache; the patient thinks he has caught a cold; pulse, 83; temperature, 99.5° F.

May 26th.—Areola desquamating; crust has dropped off, leaving healing surface beneath, without ulceration; mouth and fauces highly inflamed; tonsils very much enlarged, with white patches; no headache; pulse, 88; temperature, 99.5° F.

May 27th.—Areola desquamating; lymph still forming and drying on the sore; fauces intensely red; tonsillar enlargement diminishing; pulse, 88; temperature, 99 8° F.

May 28th.—Areola still desquamating; formation of a second crust; much itching with pain at night; throat intensely red, tonsils inflamed but diminished in size; pulse and temperature normal.

May 29th.—Areola still present; second crust still forming; tonsils and throat still inflamed; pulse, 80; no temperature.

May 30th.—Areola present, its redness fading; desquamation going on, second crust flaking off; throat and fauces red and inflamed; tonsils diminished in size; pulse and temperature normal.

May 31st.—Areola disappearing; throat still sore; all inflammation diminishing; pulse and temperature normal.

June 1st.—Areola almost faded; throat and tonsils slightly red; no inflammation; pulse and temperature normal.

At this point am I justified in saying that here, for the second time, I have inoculated a Japanese adult with scarlet-fever germs without producing the Caucasian scarlet fever. In my first attempt my germs had been obtained on the tenth day of the disease, probably too early, for, as I have already mentioned, Dr. Edington says that the most virulent period of desquamation lies between the twenty-fifth and thirtieth day. In this second attempt I have produced a condition which may or may not be a modification of the disease, but certainly is not the disease itself.

This case was exhibited, on the sixth day after inoculation, to Drs. Lester and Wolff, at the Willard Parker Scarlet Fever Hospital. I gave Dr. Lester some of the lymph from the arm. On the seventh day after inoculation the case was exhibited at the Hoagland Laboratory, in Brooklyn, to Drs. Bristow, Van Cott, and Dickinson. Dr. A. T. Bristow received various products for bacteriological culture, namely, blood from the areola, lymph from beneath the crust, and specimens of the crust itself. I have since left with Dr. Edson, Chief of Contagious Diseases Bureau, New York Board of Health, and Dr. Lester, portions of the crust. I intend to inoculate this case again with scarlet-fever germs, obtained as before, and note whether the same results will follow.

I may observe that, during the whole time of the experiment the patient was in continual relation with my own children, without any contagion taking place.

I have a half-breed child (Japanese and American), aged four, a foundling, whom I intended to inoculate with pure scarlet-fever virus. Dr. Joseph William Stickler, whose investigations in this line are well known, wrote to me in regard to this case: "I do not consider it safe to do such a thing, unless you are certain that the virus has been attenuated in strength to a degree that will render it a safe agent to use; you cannot tell prior to inoculation just how susceptible your subject may be. Hence the impression made upon the system may be very severe, or very moderate. It may be severe enough to cause death."

I therefore do not feel justified in making this attempt. But perhaps the presumably attenuated virus obtained from my Japanese subject may be used with safety.

The Kirkendall Japanese scarlet fever case, at Ithaca, and another case also in an adult, mentioned to me by Dr. Lester as having occurred several years

ago at North Brothers Island, in this city, are the only Japanese cases of the disease of which I have any knowledge. Dr. Lester informs me that there was no doubt as to the genuineness of the disease in the case which he saw. Professor James Law has written to me, on the subject of the case which occurred at Cornell University, the following letter:

"I had intended furnishing you with further particulars of the case of scarlet fever in a native of Japan, but delayed because of his protracted illness, and finally because of Dr. Kirkendall's letter. There are still some points not referred to in that letter which I think will interest you, and I shall note them so far as they have come to my knowledge.

"1. In the same house there were two cases of 'bilious' fever some time before (during last fall), and at the present time there is a case of 'tonsillitis.' The street has no drainage, and the inhabitants are confined to well-water from shallow wells, and open to grave suspicion.

"2. While it is needless to raise the question of the source of infection, when the person has been daily mingling with large numbers in public buildings, yet it may be noted that a Japanese friend of the patient had come to Ithaca to lecture, had stayed and slept with Mr. T——, and that while the two were driving near the lake the latter suffered much from cold, or had a slight chill. The friend stayed in Ithaca three days, and immediately after he left Mr. T—— was seized with the fever.

"3. The symptoms were on the whole typical: languor, prostration, headache, nausea, vomiting, high temperature, and scarlet eruption on the mouth, throat, and extensively on the skin. The urine proved albuminous, but there was at no time any indication of œdema. The affection of the throat and nose was very severe and protracted, the surface becoming raw and the expectoration largely mixed with blood. The desquamation was protracted and very extensive, the cuticle coming off from the palms and soles in unbroken sheets. Recovery was very slow and attended with great prostration and debility, the patient being confined to his room for nine weeks. Up to the present date, four months after the onset of the fever, he has not recovered his strength, and is now suffering from rheumatism.

"4. Two inmates of the house—an adult who had had 'bilious' fever last fall, and a boy, aged twelve, were removed, but the boy returned in a week, and the adult during the advanced convalescence of Mr. T——, and escaped the fever, though neither had suffered from it previously. Three students (Americans) who had not had scarlatina, and who were in the room assisting Mr. T—— during the period of nausea and vomiting (the first day of illness), were removed from the house and all escaped the fever. Mrs. W——, who believes she never had scarlatina, but who had attended her children when suffering from that disease, assisted in nursing Mr. T—— from first to last, and escaped. Two Japanese visited Mr. T—— frequently during the whole course of his illness, and showed no sign of illness.

"In connection with the immunity of the presumably susceptible Americans, it should be stated that inunctions on the skin constituted a prominent feature of the treatment. The expectorations were received in paper napkins and promptly burned.

"I have learned that Mrs. W——'s son, who had had scarlatina and who was much with Mr. T—— during his illness, afterward went to live with his aunt, and a young man in her house was attacked with scarlatina a few days later. The aunt's own children had had scarlatina a year ago, and her house was afterward thoroughly fumigated. The fact that the patient in her house showed no sign of illness for months until after the coming of Mrs. W——'s son, who had been with Mr. T—— (the Japanese), is strongly suggestive that the infection was carried from that source.

"This case of Mr. T—— seems to imply that we can educate the Japanese in other matters than are embraced in the regular curriculum, and yet the demonstration would have been more perfect had there been other cases more indisputably infected from him. If it was an instance of acquired susceptibility, it seems remarkable that it should have proved so severe, and that his compatriots, who had also had an American seasoning, should have visited him freely without any ill consequence."

In leaving this subject for the present, I feel bound to say that perhaps, after all, there is, in regard to scarlet fever, a degree of similitude between contemporary Japan and mediæval Europe, as Professor Alfred Stillé suggests in the following lines, which I extract from a letter with which he recently honored me: "Will you permit me to suggest that a different explanation may be found than that you propose, viz., that Japan has, until very recently, been segregated from other countries, and that a similar segregation appears to be the reason why the eruptive diseases of Arabia and the farther Orient were unknown in Greece and Rome, and, indeed, in nearly all of Europe until the time of the Crusades. Measles and scarlet fever were often confounded, but neither appeared in Europe until the period above mentioned."

NOTE.—Since putting the last touches to this article I received a letter from Dr. K. Takaki, F.R.C.S. Eng., Surgeon-General of the Japanese Navy, and Chief of the Charity Hospital in Tokio, in which the author, referring to my subject, remarks: "The scarlet fever has been almost unknown to us before, but about eight years ago I have seen a case in a boy fourteen years of age, among the servants of an English gentleman, and last year four cases, a lady thirty seven years of age, which was followed by nephritis; two children of my wife's fourth sister, one of them with nephritis: and at last my daughter. The symptoms of all were quite typical. This year three children of my wife's third sister have suffered from the disease at the same time. Judging by the light of these facts, I cannot say that the Japanese have an immunity, but it must be said that the disease is not so infectious among the Japanese as it is among the foreigners. On this question Dr. Baelz, Professor of Medicine at the Tokio University Hospital, entirely agrees with me."

If we consider that almost all the cases here quoted occurred in the writer's own family, and that his hospital, which I know to be one of the largest in the Empire, having been myself for two years its Foreign Medical Director, furnished him, if any, only two cases, it will appear that scarlatina is rare indeed in Japan.

4 KING STREET.

Mortality of Foundlings.—According to the Austrian Statistical Handbook, published in 1888, the total number of foundlings in Austria reported for 1886 was 42,877, of whom 5,615 died, or 13.09 per cent. of those retained in hospital, 6.71 per cent died, and of those sent outside to the country nearly fifteen per cent. died; the averages for the years 1882 to 1885, inclusive, show about the same as those given for 1886, the presumption also being that many sent from town died, but, having been lost sight of, the death did not figure on the records of the institution. As compared with the official statistics of foundling mortality in Paris, the difference is surprising. There were in Paris, in 1874, 2,171 foundlings, of whom about thirty-five per cent, or 758, died within twelve months; in 1875, 1,720 foundlings, of whom some forty per cent., or 694, died within twelve months; in 1876, 1,648 foundlings, of whom about 34½ per cent., or 568, died within twelve months; in 1877, 1,493 foundlings, of whom about thirty-six per cent., or 540, died within twelve months; in 1878, 1,880 foundlings, of whom about thirty-four per cent., or 643, died within twelve months; and of those who succumbed during this series of years, from thirty-six to forty eight per cent. in the different years died in the first seven days.

THE NEED OF A NEW CRUSADE.

ACCORDING to the cable reports the pilgrims at Mecca are suffering severely from the ravages of cholera, and, what is of far more serious import, the survivors in returning are scattering the germs of the disease throughout every Moslem country. Could the scourge be confined to Mecca and Medina, where no Giaour is allowed to enter, it would be a subject of purely philanthropic interest, and Europeans might look on with selfish unconcern; but unfortunately this is impossible. After the festival in the Holy City is ended the worshippers scatter to the four points of the compass, and carry with them to the very confines of the Mohammedan world the seeds of disease and death. Thus it is that each recurring pilgrimage presents itself as a serious menace to the entire civilized world.

This danger threatens Europe annually, but this year it seems to be greater than usual. The festival of Kurban-Bairam occurred on July 17th, and simultaneously came the cholera. The disease appeared in Mecca about July 11th, with the arrival of the first batch of pilgrims, three cases being reported that day, and increased rapidly as the number of visitors grew larger. On the 13th the number of persons attacked was 33, on the 18th over 100, and on the following day no less than 360 pilgrims were prostrated with the disease. This rapid increase in the number of cases is probably effected through the *zem-zem*, or holy water, which is doubtless a fairly pure culture of the comma bacillus, and which all drink as a part of the religious rites. The pilgrims also carry away bottles of this water to give to their friends at home, who were denied the privilege of making the journey. Could there be a more effectual mode of establishing new foci of the disease at distant points?

From all regions of Asia and Northern Africa the news comes of the progress of the scourge. It is reported to be greatly on the increase in the Hedjaz and Syria, and also in Aleppo, sixty-five deaths having been reported in the latter place on one day in August. Indeed, the disease is now diffused throughout the tableland of Asia Minor, and alarm is felt in all that part of Europe bordering on the Turkish possessions. The London *Standard* says that great consternation has been caused throughout Austria by the reports received there, respecting the terrible number of deaths from cholera in Asia and the rapid spread of the epidemic from Mecca to Northern Syria and the south coast of Asia Minor. The public concern is increased by the knowledge of the total inadequacy of the sanitary measures of the Turkish authorities. That the Turks are most anxious to keep the disease out of their European territories cannot be doubted; but the executive authorities, to whom all the measures proposed by the International Sanitary Board are intrusted, are so little to be relied upon, that neither the different cordons in Arabia nor the numerous quarantine stations that have been established are of any avail in checking the progress of the epidemic.

The sanitary condition of Mecca is simply shocking. But no Christian is allowed to enter the Sacred City, and the ignorance and fanaticism of the Mohammedans prevent any effective sanitary control by the local authorities. Burton tells us a little of what the condition of things there was at the time of his visit, and it is not likely that any improvement has taken place since. He tells of the sacrifices at Muna, when five or six thousand animals are slain and their bodies allowed to putrefy in the heat, not the slightest effort being taken to cover them with earth. Of course it would be a simple matter to inter all these bodies in holes or trenches, but, as Burton says, "the spirit of El Islam is opposed to these precautions of common sense. At Mecca, the headquarters of the faith, a desolating attack of cholera is preferred to the impiety of 'flying in the face of Providence,' and the folly of endeavoring to arrest inevitable decrees."

This threat of a cholera invasion presents itself to Europe year after year, now more and now less pressing, but recurring with the regularity of the pilgrimage itself, and it would seem as though it were time that the Western nations did something effective to protect themselves, since it has been demonstrated that the Turkish Government either can not or will not do anything. The Sultan, it is said, requested the International Sanitary Commission to take the necessary measures this summer to stop the epidemic, but the latter could do nothing in the face of the ignorance, venality, and prejudice of the authorities upon whom rests the duty of executing the recommendations of the Commission. It was proposed to send physicians to the infected districts, but the government would not provide for the payment of their salaries, so they have not been sent.

In a civilized community no individual is allowed to maintain a nuisance which imperils the health of his neighbor, and why should such a thing be allowed among nations? Since Turkey has confessed herself powerless to control her Arab subjects and to enforce upon them the observance of hygienic laws, it is time that Europe took the matter out of her hands. A new crusade with this object would afford an excellent opportunity to the great powers to work off a little of their martial spirit, and to give some of their soldiers a few lessons in warfare. Mecca is the distributing centre for cholera throughout the world, and it is even said that the disease could be stamped out in India were it not for the fresh infection brought by returning pilgrims every year. It is in Mecca that the sanitary measures should be instituted. Since the rulers of the city will not do it, it ought to be done by men of the West. And until it is done, and done thoroughly, these recurring epidemics can never be prevented. Is there no Peter the Hermit among the sanitarians?

MEDICINE AS A LIBERAL STUDY.

Some time ago it was proposed by the Harvard Medical School to have the scientific and elementary medical studies—as chemistry, anatomy, physiology, and perhaps botany—made electives for the senior year at Cambridge; so that the junior who had decided on medicine as his life-pursuit could select, in his last or senior year at Cambridge, studies which led him directly to his profession. Three years in the Medical School would then count as four, and he would graduate an M.D. one year younger than by the present method.

This present method, as we have often shown, compels a college graduate who wishes to study medicine to wait until he is twenty-two or twenty-three years of age before he can begin this study. This is often a great hardship, and practically it has had the effect of reducing the relative number of Harvard graduates who chose medicine as a calling. Despite this fact, the Faculty of the University have reported adversely on the plan. They say that this proposed method "abolishes the fundamental distinction between liberal and professional studies, and confounds all distinction between pure and applied science."

In a learned and logical address, entitled "Is the Study of Medicine a Liberal Study?" Dr. Cheevor shows the fallacy of these objections. While the study of medicine as a whole is a technical rather than liberal one, yet certain of its fundamental branches are in every true sense liberal. Anatomy, physiology, and chemistry, for example, call into play the faculties of memory, logic, induction, and observation, and they imply a wide preliminary knowledge of more elementary sciences. The introduction, as proposed, of such studies into the senior year of a classical course would be fully as helpful, mentally and educationally, as metaphysics, history, economics, or belles-lettres. The time will surely come when such introduction will be forced upon our colleges.

THE DRIFT.

Under the title "whither drifting," the editor of the *American Lancet* gives us the following interesting historical sketch. It is valuable reading.

"It is stated as an historic fact that Hahnemann was once an honorary member of the New York State Medical Society. For some reason not quite clear, those members of the Society who took up with the new doctrines, and attempted to prove or disprove them, were attacked and expelled from the Society. Being persecuted, these banded together, and hence the beginning of the distinctive organization of the homœopaths. As time passed along, some members of the profession desired to consult with these parties. Their reasons for this does not matter, though it is not denied that if there had been plenty of fat consultations exclusive of these, the desire would not have been so strong. Finally, in New York this part of the profession became so strong that they captured the State Medical Society, and conducted it upon the distinctive features known as the new code. The peculiarity of this code is its elasticity respecting consultations. Its votaries consult with any person they choose. True, a new State Society arose in New York, and maintains a vigorous existence; does splendid work —better than that of the old Society, or any other State Society. However, the new doctrine, with New York as a centre, spreads. Its influence can be seen anywhere. In every city consultations of regulars and irregulars is said to be a common occurrence. In Detroit the Homœopathic Hospital is filled largely with the patients of regular physicians. The carriages of the two sects alternate upon the adjacent streets during regular visiting hours. The Montgomery (Ala.) Medical Society has unanimously adopted resolutions favoring consultations with homœopaths and eclectics. The relations already existing between these practitioners in that State is such that it is no wonder this result follows. All this in the home of the late Dr. Baldwin, of Montgomery, the stalwart opponent of such consultations!

Columbus, Ind., has formed a Medical Society, in which all physicians meet on one common plane. It is reported that that staunch friend of the medical profession, Dr. T. A. Reany, of Cincinnati, spent an evening with this Society.

The editor of the *American Lancet* betrays between the lines a sense of apprehension and gloom. We do not share it. The tendency which he describes is a good one, and its results are beneficial. We are getting better physicians and more honest physicians every year. Sectarianism is disappearing and is bound to be abolished entirely. The test of a man will be his education, his moral worth, and his practical skill. If he has a "fad" or a dogma he will not be ostracized therefor but will be given a fair show, and time will in these days soon prove how much his views are worth.

SPINAL INJURIES IN RAILWAY ACCIDENTS.

Since Erichsen maintained that "railway spine" was a disease *sui generis* there has been much difference of opinion as to its existence, although, for a time at least, it seemed as though the affection would come to take its place in surgical nosology as an independent morbid entity. In a paper presented to the American Medical Association at its Washington meeting, Dr. T. A. Manley, of this city, presented a careful review of the subject from a surgical standpoint, dwelling especially upon the lesions of the vertebræ, ligaments, or other parts of the spinal column which may lead to serious results without any implication of the cord. He held that there was nothing peculiar in the traumatism resulting from a railway accident, and that precisely the same effects might be produced by equally severe injuries produced in other ways, and he agreed wholly with Dr. B. A. Watson, of Jersey City, that "in serious injuries of the spine, the local and constitutional symptoms resulting were always in direct proportion to the extent of spinal lesion and pathological changes existing after the accident."

In regard to the source of the spinal hemorrhage, the speaker differed from most writers on the subject, for he believed that the blood was not arterial, but came rather from the meningo-rachidian veins. Spinal hemorrhage took place within the theca, yet external to the dura, and was to be regarded as the most common cause, next to pressure from bony fragments, of meningitis.

The existence of spinal anæmia, whether resulting from railway injury or from any other form of trauma-

tism, was most positively denied by Dr. Manley. He held that anæmia of the spinal cord could occur only in cases of general anæmia, and could never exist apart from that and when other organs were well supplied with healthy blood. He also denied the possibility of myelitis occurring primarily after spinal injury regarding it as one of the later results of traumatism coming on in consequence of circulatory disturbances and the ensuing interference with the nutrition of the cord.

In short, Dr. Manley has broken a lance with those who hold to a belief in "railway spine" as a peculiar disease, and he cannot see anything in railway injuries that would make their results in any way different from those of traumatism from other sources. But do many people really believe in a pure railway spine at the present day?

News of the Week.

Somewhat Slow, but Probably More or Less Sure.—The tenth International Medical Congress still furnishes fresh matter for the columns of some of our esteemed German contemporaries, who probably think a good thing will always keep. One of them has just begun to publish one "original report" of the Section on Neurology. But even that is way ahead of the Publication Committee of the Congress itself. The latter has succeeded, after great and almost superhuman exertion, in getting out the first volume of the "Transactions," and is presumably resting now and waiting to recover its breath. Our friends of the Publication Committee should try to grasp the idea that the world "do move," and that news, like butter, does not improve with age.

Dr. John F. Keefe died at his residence in this city, August 26th, of heart disease. He was born in Ireland forty-six years ago, and came to this country when a child. He was graduated from the University Medical College in 1881.

Congress of American Physicians and Surgeons—Reduced Railway Fare to Washington.—The following instructions have been mailed to the members of the constituent societies for their guidance in obtaining a reduction in railway fares: The Trunk lines, The New York and Boston lines, the Southern Passenger Association, and the Central Traffic Association, will transport persons wishing to attend the Congress from points on their lines to Washington and return at the price of one and one-third the regular fare on the following conditions: The going ticket must be purchased within three days before the opening date of the meeting. Each person availing himself of the concession must pay full first-class fare going to the meeting, and must obtain a certificate from the agent of whom the ticket is purchased. Those holding such certificates, when countersigned by the proper officer at the Congress, can obtain return tickets at one-third the highest limited fare. Certificates are not transferable, and the return tickets secured upon certificates are not transferable. If any of them are sold or transferred they must be redeemed at the highest first-class rate by the person making such sale or transfer. No certificates will be countersigned at the Congress except those presented by physicians attending the Congress, or their wives and members of their families; nor will any certificate be countersigned after September 26th. No refund of fare will be made on account of any person failing to obtain a certificate. Those who wish to avail themselves of this method of obtaining reduction in fares, should present themselves at the office for certificates and tickets at least thirty minutes before the departure of trains. It is absolutely necessary for each passenger before starting to obtain a certificate from the ticket agent of whom the going ticket is purchased, otherwise he can obtain no reduction in the return fare There will be no stop-over privileges on the return tickets, which must always be by the same route as the going ticket. Members may obtain tickets on these conditions for their wives and members of their families, as well as themselves. Tickets for the return journey will be furnished only provided the properly countersigned certificates are presented to agent at return starting-point within three days after the adjournment of the Congress, Sunday not to be counted as a day.

A Solution of the Counter-prescribing Difficulty.—Two druggists in Chicago were recently arrested and fined $100 each for practising medicine without a license.

The New England Medical Monthly.—Ten years ago the first number of this journal appeared, and to celebrate the event the September number is issued in the form of a souvenir edition. We congratulate our prized contemporary on this tenth anniversary of its birth, and wish it even greater prosperity in the future than it has had in the past. But we must frown upon the indignity to which it subjects some of its contributors by publishing their alleged portraits. They haven't deserved such treatment.

Abandoning Medical Examinations in Life Insurance.—Three life insurance companies in Great Britain have given up medical examinations of applicants for insurance. They hope to avoid loss by giving only a portion of the premium in case of the insured's death before the lapse of a certain number of years.

Medical Fees in Marseilles Two Hundred Years Ago.—A decree of the Faculté de Médecine of Marseilles, dated in 1702, establishing a fee bill for the physicians of that place, has recently been unearthed. From it we learn that the charge for each professional visit was fixed at a quarter of a silver crown (about twenty-five cents), no discount being allowed even though several visits might be made in a day. For a consultation the ordinary fee could be demanded of one silver crown, or a dollar.

Guardians for Confirmed Drinkers.—A bill for the suppression of drunkenness, which has been introduced into the Prussian parliament, provides that every person adjudged to be an habitual drunkard shall be put under the care of a guardian who shall be held responsible for him.

A Low Death rate.—Dr. M. M. Kannon, of Los Angeles, writes us that there has been but one death during the last three years in the Sisters' Orphan Asylum of that city. The average number of children in the Asylum is two hundred and fifty-three, and their average age is under four years.

Dr. Thomas Tart Pratt died in London on Saturday morning, August 29th, at the age of fifty-two. He was born in Mobile, studied medicine in this city, and subsequently served in the war on the Southern side. At the close of the war he went to Paris, where he became associated with Dr. J. Marion Sims, and married one of his daughters. During the Franco-Prussian war he served in the American ambulance corps and rendered valuable service to the sick and wounded on both sides, in recognition of which he was decorated with the cross of the Legion of Honor by President Thiers, and with the Iron Cross by Emperor William I. At the close of the war he resumed his practice in Paris, but finally retired and went to London to live. He had been in poor health for a number of years.
